NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.—PRESIDENT'S ADDRESS.

BY EDWARD L. TRUDEAU, M.D.,

OF SARANAC LAKE, N. Y.

I CANNOT find words suitably to express my appreciation of the great honor you have done me in electing me as President of this Association. While struggling for so many years alone and in a remote region with the tuberculosis problem about me, my wildest fancy never pictured the possibility of such a widespread and earnest movement as this, and much less that I would ever be accorded the inestimable privilege of standing before such a gathering as I see here to-day as its leader. That I have been permitted to do so will be to me a satisfaction which will last as long as life does.

This, the first regular meeting of the National Association for the Study and Prevention of Tuberculosis, marks an epoch in the history of the struggle against this disease in America. It means that through knowledge has come responsibility and hope, and through both, action. The "Great White Plague" has ever been so gigantic and hopeless a problem that until recent years men have accepted the holocaust of human life which it has ever claimed, and the terrible suffering it entails on humanity, as an inevitable decree of fate, and have either looked on with oriental fatalism or turned their heads and passed by on the other side with a hopelessness born of despair and of ignorance as to the etiology of the disease.

For many years the pathologist labored faithfully and unremittingly, but unsuccessfully, to solve the problem of tuberculosis: but by the application of the experimental method, and with the birth of the new science of bacteriology, Villemin, Koch, Cornet and others, threw a light on the etiology of tuberculosis which, little by little, has inspired men with new hope and led them to the conviction that since tuberculosis is a communicable disease and its etiological factor has been discovered, it is also to a great extent a preventable one.

The realization of this truth, so vital to mankind, has come but slowly, and for the past twenty years workers in this field have struggled long and patiently to demonstrate the validity of this new hope, and to accumulate indubitable evidence as to the practical efficacy of preventive measures, while others, by improved methods of diagnosis and treatment, have demonstrated the possibility of a much earlier detection of the disease and its curability when treated by the open-air method.

I congratulate those of you who have so many years been engaged in this arduous task that your labors have not been in vain, and that at last tuberculosis is recognized generally as communicable, preventable, and, in its earlier stages and more favorable types, curable.

To this demonstration the National Association for the Study and Prevention of Tuberculosis owes its existence, and its moving force today is the hopefulness based on facts garnered in this field by individual workers during the past twenty years. This newly gained knowledge needs but to be applied in order to insure success, and it has long been evident that the efforts of individual workers can be of little avail in meeting so vast a problem—one which ten years ago would have been thought beyond the power of man—namely, the reduction of the death-rate from tuberculosis over all the United States of America. To accomplish this the National Association should be something more than a medical society devoted to the study of tuberculosis. Its watchwords should be, Organization and Cooperation; an organization so perfect and a cooperation so broad that, through education, it will bind together for the attainment of a common aim the laity, the profession, the State, and the Nation.

Abroad the value of organization and cooperation has already been recognized, and the modern crusade against tuberculosis finds European nations not as units each following its own independent path, but banded together in an International Association, with a Central Bureau in Berlin, issuing its monthly publications in three languages, and bringing together at its meetings, held at stated intervals, the best minds of medical and related professions of all countries for deliberation and consultation.

Tardily though it be, with us a beginning has been made. The United States is no longer without representation among the nations in their combined struggle with the Great White Plague, and this Association is now part of that vast international movement to stamp out tuberculosis which has been steadily spreading over the world. Organization and cooperation are the keynotes of the age, and the two main factors on which the success of the vast undertakings of modern times has depended. On their thorough application and broadest interpretation depends the degree of success the National Association will achieve. The first problem before it is to combine and direct the scattered efforts of individual workers and existing associations, and to extend and expand the field of these ef-

forts. The precise lines along which this great Society will develop its work rests with you and the future.

One of the first steps to be initiated would seem the adoption of a plan of organization that would bring each State, by means of one or more representatives, lay and professional, in touch with the National Association. To these representatives would be delegated the carrying out of the antituberculosis crusade in their respective States along the lines recommended by the National Association, making at the annual meeting their report of the progress accomplished. Through a publication of its own the National Association should keep its members in touch with one another's work and methods, and with any advances made in meeting the sociological problems which stand in so important a relation to tuberculosis, as well as in perfecting its municipal control and advancing its study and methods of treatment.

The first and greatest need is education. Education of the people, and through them education of the State. It is evident that if every man and woman in the United States were familiar with the main facts relating to the manner in which tuberculosis is communicated and the simple measures necessary for their protection, not only we might reasonably expect as a direct result of this knowledge a great diminution in the death-rate of the disease, but the people would soon demand and easily obtain effective legislation for its prevention and control.

When a State has once become well educated, and not before, will the other requisites necessary to the control of the disease be forthcoming. These requisites are briefly, a higher standard of public hygiene and improved conditions of life for the masses; sanitary laws embodying the municipal control of tuberculosis as it is now understood; the segregation of the tuberculous in public institutions and prisons; the establishment of sanatoriums for incipient cases; hospitals for advanced and hopeless ones who cannot be cared for safely at their homes; specially organized dispensaries, laboratories for research, etc.

Education should begin by teaching in the public schools the main facts relating to the transmission of tuberculosis, insisting in such teachings on the value of hygienic measures of prevention, and dwelling as little as possible on the details of the bacteriology of the disease, which would tend to produce in imaginative young minds exaggerated and fantastic impressions of the dangers of infection; education of the masses by distribution of suitable literature, by lectures to trades unions and various organized bodies, by free museums, tuberculosis exhibitions, and through the medium of the public press and periodical literature. Education, by teaching just where the danger lies and the simple measures necessary to avoid it will tend to quiet and control the unreasoning and ignorant terror of infection which often works such hardship and injustice to the consumptive. Early detection of the disease is the first requisite for success in its treatment, and it is through education alone that incipient cases will be induced to seek advice early and to make at the right time the sacrifices necessary to bring about their recovery.

Education will help to crush the vampire of quackery which preys ever on the misfortunes and ignorance of the poor consumptive, appealing with devilish ingenuity, through spacious advertisements of mysterious specifics and sure cures, to his credulity and hope, masquerading under the guise of science and even of philanthropy, in order to wring from him his small savings, and then casting him off, when these have been exhausted and his disease is well advanced, doomed to a lingering death, helpless, hopeless, and a heavy burden on the overtaxed resources of a charitable community. May the time soon come when the National Association will be in a position to put its heel on the demon of quackery, not only by educating its victims, but by applying its large resources and influence to bring the offenders to justice.

Educational measures should not be confined to the public, but, along different lines, extended to the profession as well. Medical schools should be urged to give special didactic and clinical instruction in advanced methods of making an early diagnosis. In graduating from most medical schools the young practitioner is too apt to carry with him the picture of tuberculosis as he has seen it in the advanced cases usually shown at clinics and dispensaries. Incipient tuberculosis he has not been taught to recognize. On the general practitioner and the dispensary physician rests the great responsibility of detecting the disease in its incipiency, for it is to them and not to the specialist that the patient first applies. Not by lectures alone, but by clinical instruction as well, should medical students be taught how to detect the varied and insidious onset of incipient tuberculosis, impressing on them the curability of the disease in its earlier stages, and for this reason the responsibility of making a diagnosis before the classical symptoms of pulmonary consumption develop. The various sanatoriums offer such rich opportunities for clinical instruction in incipient tuberculosis, early diagnosis, and treatment, that summer courses could, with great advantage, be given at these institutions.

The value of the tuberculin test when applied to cases where a positive diagnosis cannot be made by ordinary methods has not yet been fully recognized, and in my experience its unreliability and dangers have been much exaggerated. A method which enables the physician to reach a positive conclusion as to the presence or absence of tuberculosis long before it can be done by ordinary clinical methods is of such vital importance in all attempts at curing the disease that it is to be hoped the National Association will be a me-

dium through which a more exact knowledge of its scope, its limitations, and its real value, may be reached.

The practical application of knowledge already gained as to the measures briefly touched upon, and which represent prevention, is one of the two great responsibilities of the National Association. The other is the extension and advancement of the study of tuberculosis in this country. The United States, at any rate so far as tuberculosis is concerned, should not much longer justly lie under the imputation of being "one of the largest borrowers in the scientific markets of the world." Already everything points to an awakening to the need and possibilities of original research in this country. Within the past five years the Carnegie Institute, the Rockefeller Institute, and the Phipps Institute, have been founded and generously endowed. Many laboratories have been opened in connection with colleges and hospitals, and journals and societies devoted to original research have sprung into life, so that before many years American Science will have won its place in the world's scientific advances in the field of medical research. The scientific study of tuberculosis, however, offers so broad a field, and one requiring observations extending over such long periods of time, that special permanent endowments solely for researches in tuberculosis, which would enable experimentation in this field to be carried on continuously through a number of years, are greatly needed.

In time the sanatoria can furnish, from carefully kept records extending over many years, valuable data hitherto unattainable, bearing on the history, varied clinical manifestations and treatment of the disease, and improvement in methods of municipal control will steadily develop along the lines already so wisely instituted.

But it is mainly to the laboratory research work that we must look for the solution of many of the as yet unsolved problems of tuberculosis, and for advance in our methods of prevention and treatment. The study of different sources of infection; of the great variations of virulence in tubercle bacilli and how brought about; of the different species of the tubercle bacillus and of related bacteria; their relation to each other and to the disease; the chemistry of their toxins; and, above all, the mechanism of natural immunity and the possibility of producing artificial immunity to the germ and to its toxins; the mechanism of such an artificially induced resistance, are but a few of the subjects of the utmost interest at present, on which the laboratory alone can throw much needed light.

Although artificial immunization against tuberculosis has hitherto been looked upon as a dream never likely to be realized, during the past ten years a great deal has been added to our knowledge of the mechanism of natural and acquired immunity against infectious diseases, and appreciable advances have been made in producing in animals a relative degree of artificial immunity against tuberculosis. If further researches are ever to result in some safe method of inoculation that will produce artificial immunity, or even greatly increased resistance to tuberculosis infection, it is to the laboratory that we must look for such an achievement.

Along these lines, laid down by its founders, and which I have briefly touched upon, the National Association for the Study and Prevention of Tuberculosis bids fair to work out its destiny.

On the spirit of a work like this depends its life and success. The motive which has brought you together, and the spirit which has made possible the existence of the National Association, is to my mind the best guarantee of its success; for its work represents the highest type of unselfish human endeavor and the highest aim of a noble profession; namely, the struggle for the existence of others—a struggle which will not be rewarded even by the gratitude of those whose lives you will save, for they will never even know that they have been saved.

If the National Association succeeds in coordinating and binding together in one sustained and well-directed effort the scattered energies which have sprung into life all over this great country, if it can secure the cooperation of the sociologist, the legislator and the philanthropist, if its organization is complete and its members have become imbued with the greater meaning and true spirit of cooperation—a cooperation ever ready to sacrifice selfish aims to the success of a great cause—a cooperation which to the athlete means team work and to the soldier discipline—it cannot but prove a powerful instrument in the struggle against tuberculosis in this country.

It has been said—"the degree of civilization of a people will in time be indicated by the figures of its death-rate." If this be so the National Association has indeed a great responsibility; one which it nevertheless seems well fitted to assume.

THE EDUCATIONAL TREATMENT OF "TICS."[1]

BY B. SACHS, M.D.,

OF NEW YORK;

ALIENIST AND NEUROLOGIST TO BELLEVUE HOSPITAL; NEUROLOGIST MT. SINAI HOSPITAL, NEW YORK.

IT is my purpose to call attention to some recent views regarding the effective treatment of tics. The change in therapeutic principles has been brought about largely by a change in the conception of the disorders in question, and we cannot discuss the former intelligently or satisfactorily without dwelling for a very few minutes upon the essential nature of "tics" or "habit-spasms."

Everyone who has been called upon to classify functional disordered movements has found great difficulty in distinguishing between "tics," habit-chorea, general choreiform movements, myoclonia, paramyoclonus and the like. The subject is complicated by the suspicion of hysteria, which often arises; then again "reflex

[1] Read before the N. Y. Academy of Medicine, April 20, 1905.

neuroses" have been made to include tics and many choreiform movements, and yet none of these is ever truly reflex in origin. If the entire series of reflex neuroses were eliminated from neurological text-books, neurological science would be none the worse for it. As a matter of fact, there are, to my mind, no reflex motor neuroses in the physiological sense, *i.e.*, a peripheral sensory irritation carried centripetally and resulting in a centrifugal motor impulse.

To clear the atmosphere, it may also be stated at the outset that tic douloureux is an old-fashioned designation—an unfortunate misnomer—and has nothing whatever to do with true tics; even the facial spasm observed particularly in the senile period does not belong to the class of cases to which we are to give some thought. The advance in our knowledge of habit-movements is due chiefly to the French school, beginning with Charcot and Noir and ending with Brissaud, and his pupils Meige and Feindel, who have written an excellent monograph of over 600 pages on tics and their treatment. The subject was discussed at the Twelfth Congress of French Alienists and Neurologists in 1902; Noguès, Grasset, Pitres, Ballet, Cruchet, Crocq and others giving their views with all the accuracy and picturesqueness of description so characteristic of French clinical writers. There can be no doubt, on the other hand, that the older writers in Germany, France and England, Friedreich, Trousseau and Gowers, for instance, recognized some of the peculiar features of this special group of disordered movements, and Oppenheim had anticipated some of the conclusions reached by the physicians of La Salpetrière. In this country Osler has at various times attempted to classify and to describe the various forms of tics, and Dana and myself have also struggled with the subject.

According to our present-day conception, tic is an involuntary movement which can for a time be controlled, or even inhibited, by the will. We have had to borrow the term from the French, as the Germans have also done. The spirit of our language will not sanction the adoption of some of the French derivatives. The victim of tic is called a "tiqueur." If we were to publish the records of a "ticker," as the French have, we might be accused of irrelevant, if not unscientific studies. The only proper English equivalent is habit movements or habit-spasm, but the French have endeavored to differentiate between tic and spasm and are inclined to discard the latter term.

Brissaud, for instance, claims that a spasm is "a motor reaction (say movement) resulting from irritation of some part of the spinal or bulbo-spinal reflex arc. The irritation which excites this spasm is produced by some morbid cause, and may be either peripheral or cortical." In this sense spasm is a true convulsive action, a muscular contraction rather than a movement.

Tic is a coordinated or systematized movement with a definite object in view, repeated frequently and in exaggerated fashion. Frequent repetition of such movements creates the habit, and the habit once established, the movements become automatic.

Meige has made a fine point in this discussion by showing that tics are concerned with functional movements and chiefly with such which are partly reflex and partly subject to the will (habit winking, habit cough). Most of these tics have been purely reflex movements at the start; the reflex actions are voluntarily repeated and through frequent repetition become automatic, just as the child at first has to learn the movements necessary for walking or in writing. As it repeats these exercises again and again the movements, though conscious, become more and more automatic. Guinon claims that tic is a conscious movement at all times. Lutulle protests that it is an unconscious act. Meige and Feindel have endeavored to harmonize these views by stating that the patient is conscious of the tic before and after the movement and not during the act. That distinction is a subtle one indeed, whereas the chief point would seem to me to be not whether the movements are conscious or unconscious, but whether they are intentional.

When a tic is firmly established the movements are not intentional. It is certain that they could be suppressed if the will to do so be strong enough and be exercised to that end. To a very limited extent I believe this to be true also of choreic movements except those dependent upon organic disease. The power of control is not so strong as is the motor impulse and it is this abnormal psychic condition which is the controlling factor in the genesis of tics. "The very essence of a tic is that it is an abnormal motor manifestation dependent upon an abnormal psychic condition."

We have seen that a tic may be the habitual repetition of a normal function, habit-winking, habit-coughing, respiratory spasm, etc., but it may also be concerned with a new function discovered by the individual, as the Frenchmen say. Thus, one patient of mine discovered that by throwing his head backward he could produce a crackling sound in the nape of the neck, he repeated it again and again until the habit of throwing the head backward became an irresistible impulse and his special form of tic was firmly established. When once established the patient was able to subdue the movements in part, but it was a great strain upon him to inhibit them altogether. The attempt to check them caused the patient to break out in profuse sweat and to get into an extreme condition of general motor restlessness. Everyone who has observed such patients will grant that it is a struggle of no mean order to endeavor to check a full-fledged habit-movement. The vigor of the contractions, and the inordinate frequency of repetition are the special characteristics of these motor abnormalities.

If tics were oddities merely of muscular contraction, we might dismiss them with a word or two and with a regret that they are so difficult to cure, but they have a far deeper significance. They at times are often associated with mental disease and with evident psychic and motor disturbances; they are the first expression of mental degeneracy. They may be developed early in life, even in very young children, and if not seriously dealt with, will lead to disastrous results. Parents are too fond of admiring the tricks of their little ones, but if tricks are "tics," it will be well to put an end to them as soon as may be. The simple tic may effect any group of muscles; those of the face and neck including the platysma, are commonest. They are not merely muscular contractions, say of the frontalis of the orbicularis oris, or of the orbicularis palpebrarum, but they are the more complicated movements of winking, snuffling, whistling, shrugging of the shoulders, twisting of the neck, and soon, in children, we also observe tics "consisting of screaming, snapping, scratching or biting habits." Speech habits or speech tics are very distressing.

A few weeks ago, a boy seven years of age, was brought to me from the western part of the State, whose only symptom was a loud explosive noise which he emitted at least ten or fifteen times every minute. He was an only child and quite beyond parental control, as such children often are. There was no perceptible clonic movements of the diaphragm and no tangible cause for the explosive sounds. There was nothing choreic about the child. I proposed definite discipline and educational treatment, but the parents knew better and were certain that fresh air would cure him. By accident or otherwise this boy may have discovered that he could produce such a sound and a few repetitions after this discovery were all that were necessary to start him upon the habit.

During this present week I have seen another child, two years and nine months old that had been born with instruments but had remained entirely normal in spite of this and had no convulsions, was a bright baby and began to utter a few words at the early age of eight or nine months. During the second year of its life it had head-nodding (gyrospasms), an infantile incoordination of movement which differs from others only in this that it seems to disappear spontaneously. The parents of this child, who are intelligent and careful of their first offspring, have noticed of late that while the child speaks well it halts every now and then and has retarded and then explosive articulation—a true speech tic which will have to be checked promptly if the child is not to form the habit.

As I have said, these speech habits are not uncommon. An old student friend of mine, who has since become a celebrated astronomer, was in the habit of winding up every sentence with a rising inflection and the usual interrogatory utterances, "Hm, ah, eh?"

You will notice that we pass easily in a consideration of this subject from entirely motor phenomena to those of a psychic or psychomotor type. The chief difficulty is that there is not sufficient strength of will to check the developing habit. Many of the cases of torticollis are explained, and the French thus have invented the term "mental torticollis" for such cases.

Some years ago a bookkeeper visited my clinic who had been in the habit of transferring accounts from one ledger at his left to another upon his right. Hundreds of times during the day the head was turned quickly from left to right, the habit became established and the movements could not be suppressed after working hours. The result was a true and an annoying condition of "spasmodic" torticollis. Some improvement followed upon the directions given him to rest the head on a support so as to prevent the movements, and to turn the head forcibly in the opposite direction.

In addition to all these simple tics we have those, as Osler put it, with "superadded psychic phenomena." The "maladie des tics convulsifs," Gilles de la Tourette's disease, is characterized by a facial tic, by other tic movements, by explosive and often foul utterances (copralalia) by repetition of words and actions (echolalia and echokinesis) and by imperative concepts. These utterances are as uncontrollable as are the phychic phenomena. The impulse to repeat definite words (peculiar gestures, etc.), the doubt as to whether the light has been turned out or the letter sealed, the fear of using a knife, of crossing the street, the impulse to pick up every scrap of paper, every pin, all those imperative ideas and imperative impulses are the psychic equivalent of the motor phenomena, and the psychic symptoms are as little under control of the will as are the muscular contractions.

Sufficient has been said, I believe, to show that the tics are not merely psychomotor phenomena, but that there is a peculiar disturbance of the will, which is mainly responsible for the persistence of the habit-movement.

In former days the treatment of this condition presented great difficulty. The ordinary sedatives and the various surgical procedures which were resorted to for the cure of some of these tics were wholly unsatisfactory. The patients were eager enough to be rid of their habits and often became intensely discouraged over complete failure of treatment.

The pedagogic or educational treatment is based entirely upon the idea that the disordered psychic and motor functions must be disciplined in various ways. The French speak of this as the "traitement reeducateur." Oppenheim claims superiority for his plan and states that the one feature omitted in the French method and included in his own is the inhibition therapy. I should like to call this pedagogic treatment common-sense treatment, and I am certain that all of us have practised it for years, but it is well to

have it put before us with a more impressive title. In all of my own cases I have insisted for years back and have made mention of this in my book, that the patient be made to stop the movement if he can, and that he perform systematic movements entirely opposed to those involved in the tic, but it is a mistake not to give dignified names to therapeutic procedures. You may tell your patient to sit in the open air for hours at a time, and yet he will not do as well as he will if subjected to "air baths," as administered at various German health resorts. To be sure the air bath is given in the woods and the patients are encouraged to disport themselves nymph-like, under proper surveillance and the protection of high fences. Just so the treatment of tics will be very much more efficient if both the physician and the patient know that the method of treatment has a special designation. I am far from underrating the value of this and think we might occasionally take the hint from the practices of our European confrères who for methods which we do not always dignify by special names use the terms "psychotherapy," "aerotherapy," and the like. Let us see what pedagogic treatment offers us in the case of tics.

The principles of this educational treatment, as laid down by Brissaud, are as follows: "The immobilization of movements" and "movements of immobilization," which translated into ordinary language means the movements are to be stopped and the patient is to perform other systematic exercises. There is to be an absolute immobility, to quote the French phrase again, "a photographic immobility" of face and limbs during an increasing period of time. The patient is to sit as though he were looking into the camera. At the first sitting he is to preserve this absolute immobility for one, two or three seconds. At each sitting a second or two are to be added and thus little by little the time of absolute quiet of all muscles is to be increased. By patient endeavor the victim of tic can manage to pass an entire hour without the slightest abnormal movement. A point of some importance is that the patient should be told in advance exactly how long the session is to last. He is to sit in a comfortable position and should be encouraged by word of mouth that he *should* and that he *can* remain immobile. In other words, the effect of suggestion and of encouragement is to be added and there is no doubt that such suggestion and assistance as may be given him in this way will make his task an easier one. If the tic patient and his physician,—a French author says,—"will form an offensive and defensive alliance against the tic, and if they will remain united they will triumph." Even though there be a tremendous solemnity about all these injunctions some good will unquestionably come of them. After this period of immobility is passed the patient should be subjected to well-disciplined movements particularly of the muscles in the region in which the tic occurs.

The entire sittings are to be of short duration and to occur several times a day. At least one sitting a day should, if possible, be directed by the physician himself. If the patient is asked to do the exercises by himself, he should perform them before a mirror so that he may have his attention riveted upon them and may be able to determine whether he is doing them correctly or not. Long after the attack has actually ceased, the treatment, more particularly the methodical gymnastic exercises, should be continued.

In addition to these exercises it is important to lay down a daily routine, just as we in this country are accustomed to prescribe during the various stages of a rest cure. For my own part, I believe that if this educational plan of treatment is to be a success it can be carried out only at a private hospital or in the home of the patient, if the patient can be isolated and be placed under the care of a competent nurse or younger physician. The exact exercises will vary according to the special character of the tic. If the patient has been subject to habit winking he is to be ordered to close his eyes, to open them, to keep them closed a definite length of time, to open them for a definite period, to close one eye and then the other. At the same time order him to open and close the mouth and if there happens to be a tic of the mouth associated with habit winking, as is so often the case, let systematic movements of the lips be carried out, and in such cases it would be well to order the patient to read aloud in a very slow fashion. It is best perhaps to make him read verses and ask him to read them most distinctly and with definite rhythm. Each case should be studied on its merits and the exact nature of its movements, particularly of antagonistic movements must be dictated by the physician. In a case of facial tic of the eyes and of the mouth the following is the program prescribed by Meige:

"Every day and three times per day at the same hours, nine o'clock in the morning and one o'clock in the afternoon, and at six P.M. the patient is, during two minutes, to stare at himself in a fixed manner before a mirror observing absolute immobility of his features. During two minutes he is to read aloud, during two minutes to speak before the glass and during another two minutes to walk up and down before the mirror. This was to be repeated three times during the day and if during any exercise an attack appears he must commence over again once or twice; if a third time is necessary he must stop and not resume until the following sitting." In the treatment of speech tics (I have no doubt many cases of incipient stammering can come under this heading), it is important to submit the patient to definite vocal exercises, making him first of all perform those which seem most difficult, teaching him to prolong vowels, to speak slowly, laying stress upon the articulation of each syllable, and finally to get the

patient to read aloud phrases, then sentences, then short stories, and so on. This same method has long since been followed by many teachers who pay special attention to the education of stammerers and of those having other speech defects. In these latter cases the ordinary calisthenic breathing exercises will be of great assistance.

I have said enough, I believe, to convince you that in reality this pedagogic method does not contain anything distinctly new, but some credit is due to the various writers who have taken the trouble to give the minute details of treatment, and I have no doubt that the success attending the educational treatment of ties will be just as great as has been that which attended the employment of the definite methods outlined by Fraenkel, of Switzerland, which we now employ universally in the treatment of locomotor ataxia. The special point about the educational treatment of tics is that it is based entirely upon the influence which the mind is known to exert over these irregular movements and as the method is directed entirely to the development and strengthening of such influence it is surely worth our while to study the method and to practise it carefully.

LAVAGE OF THE RENAL PELVES IN THE TREATMENT OF BRIGHT'S DISEASE.

BY WINFIELD AYRES, B.SC., M.D.,
OF NEW YORK;
ADJUNCT PROFESSOR OF GENITO-URINARY SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

My experience in the treatment of Bright's disease by lavage of the renal pelves is far too limited to determine absolutely the uses and limitations of the procedure, but it has shown me that much good may be accomplished by its employment in selected cases if the ureters be properly catheterized and the lavage carefully given. On the other hand, if the treatment be not carried out with the utmost care and attention to detail, no benefit will be derived from it and the patient may be made much worse.

Last June, in a paper read before the American Urological Association, at Atlantic City, I stated that beginning nephritis could be cured by lavage of the renal pelves and suggested that even certain of the more advanced forms of nephritis might be improved by resorting to this treatment. I also stated that in chronic interstitial nephritis, where contraction had already begun, lavage of the renal pelves could not possibly do any good. Nine months of additional work in lavage of the renal pelves has shown me that I was right in my prognosis and I have found that chronic parenchymatous nephritis that has not reached the stage of contraction is wonderfully improved, whereas contracted kidney, whether the origin was a parenchymatous or interstitial nephritis, is not improved and often made worse by lavage.

In February, 1904, one of my patients, whom I was treating for chronic urethritis, was found to have marked pyelitis together with a beginning Bright's disease. His urine contained in addition to pelvic epithelium, a small amount of albumin, many cells from the tubules of the kidney and a few hyaline and granular casts.

To cure his pyelitis, he was put under treatment by lavage of the renal pelves, and much to my astonishment, the casts, albumin and tubule cells disappeared from the urine in a very short time. Since then I have treated a fairly large number of cases of nephritis in all its various stages, by lavage of the renal pelves, and the purpose of this paper is to present the results of such treatment in so far as I have gone.

The various causes of nephritis, as enumerated by different authors, are circulatory, as in heart disease; irritants or poisons circulating in the blood as the various drugs, faulty metabolism resulting in lithemia, etc., and irritants not yet determined; and the extension of inflammation from the renal pelves. The latter cause for inflammation in the kidney, it seems to me, has not been sufficiently investigated and we will in future find that many cases now ascribed to unknown irritants are really due to extension of inflammation from a pre-existing pyelitis.

Strümpel says: "If we look for etiological conditions in cases that have a chronic course from the beginning, we can often discover nothing at all. The disease seems to have developed of itself in previously healthy persons." He thinks there is probably some "unknown toxic or infectious agency that acts on the kidneys." Opposed to this I wish to give the results of my work in the renal pelves in the treatment of catarrhal pyelitis. I have treated 142 patients suffering from this condition who gave no symptoms of nephritis. Of these, 46 had more or less involvement of the kidney, as shown by the chemical and microscopical findings. In all probability the inflammation would have continued and extended in the majority of these 46 cases until well-marked nephritis would have been recognized by the symptoms present. It is quite probable also that in many of the 96 cases who had no kidney lesion the inflammation would have extended to the kidney structure. It is this class of patients in whom the chronic nephritis seems to have "developed of itself in a previously healthy person."

Catarrhal pyelitis may exist for a long time without causing the patient much discomfort; and the few symptoms that are complained of may be ascribed to indigestion, rheumatism or lumbago. One of my patients who had pyelitis with slight involvement of the kidney had had his back cauterized several times without benefit for what had been diagnosed as lumbago, yet two treatments of the renal pelves by lavage entirely relieved the pain in the back.

In speaking of the cause of interstitial nephritis, Tyson says: "Long-continued cystitis, especially following gonorrhea, is undoubtedly a

cause in a few instances, the inflammation traveling up the ureter to the pelvis of the kidney and thence to the intertubular tissue." Strümpel does not mention the variety of inflammation that is caused by ascending inflammation. He says: "One way in which the morbific agent may also enter is especially important—namely, from the lower urinary passages, the bladder, and the pelvis of the kidney, upward into the kidney." Two quotations from Strümpel which bear directly on the etiology are, first: "The anatomical changes of acute nephritis show a continuous series from the mildest to the severest degrees, according to the intensity of the injurious action. The mildest changes, which, as we have said, are not called actual 'inflammation,' but usual simple parenchymatous degeneration affect exclusively the parenchyma of the kidney—that is, the epithelium—while the interstitial tissue, the connective tissue, and the vessels remain perfectly normal. This fact is of prime importance, since it implies that, in almost all the injurious influences acting on the kidneys, the specific renal parenchyma itself is diseased first and before the other." Again: "There is no essential distinction between the anatomical lesions of the kidney in acute and chronic nephritis. The changes that are seen are essentially the same, only they develop and extend more slowly in the chronic forms."

If we find among young men a considerable number of cases of catarrhal pyelitis with slight invasion of the kidney, as shown by the presence in the urine of degenerated tubule cells and perhaps a little albumin, we have already found the chronic parenchymatous degeneration of Strümpel, and later these same patients will probably have occur in their kidneys the interstitial changes that are found in every case of advanced chronic Bright's disease. I think if the subject is studied more closely with relation to a pre-existing pyelitis that the origin of many a case of Bright's disease, which apparently began "of itself," will be explained. If this prove to be correct, the percentage of Bright's disease recognized as having originated from a gonorrhea, will be markedly increased. It will also, to a certain extent, account for the fact that there are more cases of chronic nephritis in men than in women, because gonorrhea is more frequently followed by cystitis in the male.

I have come to regard the presence in the urine of degenerated epithelium from the renal tubules on repeated examination, whether albumin is present or not, except in floating kidneys, as indicating a beginning nephritis. We not infrequently find tubule cells in the urine simply due to the irritating effects of the oxalate of calcium or to uric acid, but these cells quickly disappear from the urine after the oxalates or uric acid have been eliminated, if there is no nephritis present. The cells are also much less degenerated in appearance when due to irritation than when due to inflammation. In all urinary analyses I believe the sooner the examination is made after voiding, the more accurate will be the findings.

In speaking of these cases I shall refer to beginning nephritis as parenchymatous degeneration. The pronounced cases will be called parenchymatous or interstitial nephritis according as the parenchyma or interstitial portion of the kidney seems more involved. And yet the two forms are so closely allied that it is sometimes almost impossible to differentiate one from the other.

I have treated 46 cases of parenchymatous degeneration and in all but eight the tubule cells and albumin have disappeared from the urine. Six of these eight are still under treatment, the other two having discontinued treatment upon the relief of the symptoms for which they consulted me. Among these 46, there were six who had casts, both granular and hyaline, in the urine. They had passed the stage of parenchymatous degeneration, but the nephritis was not so pronounced as to class them among the advanced cases. Every one of these six has been discharged cured, the urine having remained free from all evidence of nephritis for quite some time. I have watched four of these six for a period of from three to four months and there has been no indication that the inflammation had or would return.

Of the other 38 cases of beginning nephritis all presented tubular epithelium in the urine. Sixteen had no albumin and 22 showed more than a trace. The time required to cause the tubule cells to disappear varied greatly. In some, two weeks were sufficient, whereas, in others, and these were the ones who had the largest amount of albumin, these cells persisted for twenty weeks. The longest time required to cause the albumin to disappear in these mild cases was eleven weeks and the shortest, one treatment. In the latter case the albumin was not found after first treatment, but the tubule cells persisted for four weeks. Nearly all of the 38 cases remained under treatment for pyelitis or some urethral, prostatic or vesicular inflammation for some months after the trouble in the kidneys had been relieved and I was able to watch them closely and in not one was there evidence of a return of the inflammation in the kidney. I think I am safe in saying that they have been prevented from developing a typical case of parenchymatous or interstitial nephritis later in life.

I have treated 12 cases of advanced nephritis by lavage of the renal pelves. Three were chronic parenchymatous nephritis and were markedly improved. Their histories are appended. Two cases of mild interstitial nephritis were somewhat improved. One case of marked interstitial nephritis was considerably improved at first, but the treatment had no ultimate influence on the course of the disease. Three cases of well-marked interstitial nephritis were not in-

fluenced; neither were two who had had decapsulation performed. One patient in the late stages of interstitial nephritis was made much worse by the treatment. From this record it is seen that lavage of the renal pelves for Bright's disease is applicable only in selected cases; and the diagnosis is all important. Even with the utmost care we are not always capable of judging of the absolute condition of the kidney by the urinary and physical examination, and some cases that appear hopeless may respond to the treatment by lavage, while others, with everything apparently favorable, will not be influenced.

The question always arises as to how the beneficial action is brought about. Why does improvement in the condition of the kidney occur when the lavage only reaches the renal pelves? I have seen the improvement, but as yet have found no explanation that is satisfactory. For the first few treatments, immediately after lavage, the patient experiences a feeling of general malaise which lasts about an hour. This is followed by a feeling of well-being that lasts from two to three days. For from one to three days the urine is markedly increased in quantity and then slowly returns to the normal amount. For want of a better explanation I have attributed the improvement to the cleansing of the renal pelves of the products of inflammation, the establishment of better drainage from the kidney and the counterirritation of the ureteral catheter and the counterirritation to the kidney by the use of a hot, slightly irritating, solution in its pelvis. It is possible that the lymphatics of the kidney take up some of the antiseptic solution and carry it through the organ and the beneficial action occurs from this.

To follow a chronic nephritis from its inception to its termination is impossible. There are a large number of cases that have as their origin some nephritic irritant circulating in the blood, but there are a still greater number in which no such irritation can be found. It is my belief that a large per cent. of the latter cases are due to extension of inflammation from the renal pelves. The cause of the pyelitis may have been an ascending inflammation from the bladder or it may have been the irritating action of uric acid or oxalates. If we wish to guard our patients from the possibility of Bright's disease later in life, it is essential that we investigate all our urinary cases very thoroughly; even such an apparently slight thing as pain in the back should not be passed over lightly. The urine should be examined in every case. If pelvic epithelium is found, the renal pelves should receive appropriate treatment, thus preventing invasion of the kidney. The following case illustrates the necessity of a careful urinary examination:

Case I.—C. L., aged thirty years; married; was referred to me by Dr. Glinnen May 9, 1904. He said that he had never had gonorrhea and had had intercourse with no one but his wife since marriage. About three weeks before he was sent to me he had noticed a discharge from the urethra. This discharge continued in spite of medication and injection. When I first saw him he had mucopurulent discharge of moderate severity. A smear taken the meatus did not show the presence of the gonococcus. Both urines were quite cloudy and the microscopical examination disclosed the presence in the urine of a moderate amount of pus, and epithelium from the urethra, the prostate, the seminal vesicles, the bladder, the ureters, the pelvis of the kidney, and from the tubules of the kidney. A small amount of albumin was present. He had, then, a catarrhal pyelonephritis, ureteritis, cystitis, gonocystitis, prostatitis, and urethritis. His urethra, prostate, vesicles and bladder were treated according to the ordinary method for curing inflammation of these organs, and he was given internally the different urinary antiseptics. His diet was carefully regulated. After six weeks of thorough treatment there was only a slight decrease in the amount of his discharge and the cloudiness of his urine was only slightly lessened. I began lavage of his renal pelves on June 24 and continued it twice a week for four months. The albumin entirely disappeared at the end of two weeks and the tubule cells at the end of seven weeks. Nine weeks later no epithelium nor pus had been found in three successive treatments and his pyelonephritis was pronounced cured. He continued under treatment for three months longer for inflammation in the prostate and was then discharged cured. During those three months the urine was repeatedly examined for renal epithelium and none was found. It is possible that in time something could have been found to have stopped his discharge, but no medicine that I tried had any effect in reducing the number of epithelial cells from the renal pelves and tubules. And it is probable that the inflammation in the kidneys would have progressed steadily and that he would have developed a marked parenchymatous or interstitial nephritis. I was never able to determine the absolute cause of the inflammation in this case.

Case II.—L. K., single; aged thirty-five years; cigarmaker; was referred to me by Dr. Wolbarst, who had been treating him for stricture and prostatitis. I saw him for the first time on June 26, 1904. He said that he had had several attacks of urethritis, none of which had been very severe. He had had several attacks of renal colic, the first occurring thirteen years ago. He complained of a constant boring pain in the back and of frequency of urination, being compelled to pass water every two hours by day, but none at night. Examination showed the urine to be slightly cloudy in both specimens, the first containing a few prostatic points. The urethra was of normal caliber, but at two points slightly thickened. Prostate normal size, but soft and

flabby. Microscopical examination disclosed the presence in the urine of a very large number of cells from the renal pelves and many from the renal tubules. A small amount of albumin was present. He was given his first lavage June 28, and the treatment was continued twice a week until January 20, 1905, when the inflammation in his kidneys was declared cured and he was returned to Dr. Wolbarst for further treatment of the prostate. The albumin had disappeared in the fifth week of treatment and the tubule cells in the ninth. A peculiar feature of this case was that after the first few lavages he passed large phosphatic concretions, about the size of pinheads. After a month no more were seen. They were not large enough to be called calculi, but were probably the cause of his renal colics. He came in to see me March 3. He has no pain and no frequency. His urine is absolutely free of kidney epithelium and he is undoubtedly saved from a further extension of the inflammation in the kidneys.

These two cases will serve to illustrate the effect of lavage of the renal pelves in treating chronic parenchymatous degeneration, or beginning Bright's disease.

Case III.—Typical case of subchronic parenchymatous nephritis without tendency to cirrhosis. Cause, probably ascending inflammation from the bladder. W. H. S., aged thirty-two years; clerk; came to the office June 20, 1904. His waxy ears, lips and complexion, with dulness of eyes and general appearance showed him to be in the last stages of parenchymatous nephritis. He had had a urethritis fifteen years previously, but considered himself cured. In August, 1903, he had had pains in the back which had been ascribed to rheumatism and indigestion. In September he began to have headaches. The indigestion became worse, was temporarily relieved by essence of pepsin, but the headaches continued. At about the same time he began to be troubled by insomnia and nervousness. In December the headaches had become more frequent and severe. He felt languid and indisposed to exert himself; had no appetite; nausea in the morning; buzzing in the ears; pain in the back; puffiness under the eyes; spots before the eyes. All these symptoms continued until March, 1904, when he apparently had an acute attack of nephritis after exposure to cold. From that time until I saw him he had had considerable edema, at times becoming very marked, with all the other symptoms that usually accompany parenchymatous nephritis. During May he had had three attacks of uremic convulsions. He had been troubled constantly by dyspnea on exertion, and at times had had considerable nausea. He said there had been a constant uriniferous odor to his body. He was unable to walk over two blocks without resting and said that it seemed impossible for him to stoop to pick up his shoes. From March until June 13 he had not worked, but had spent the major part of this time in bed. He had visited several of the mineral springs and had been somewhat improved. When he came to me he had been at work one week and during that time had failed rapidly. Often while at his desk he would be seized by an attack of dizziness and have to grasp the desk to keep himself from falling. His face and ears were waxy; eyes lusterless; lips almost of the same color as the face; nose pinched. There was marked edema of the legs to above the knees and edematous area over the sacrum. His normal weight was 117 pounds, but on June 20 was 121, the increase he attributed to "water." The pulse was 88 and fairly high tension. Heart moderately increased in size; first sound roughened, second sound accentuated. Quantity of urine said to be 50 to 60 ounces per day. Urine quite cloudy; sp. gr. 1.020, and solidified on boiling. Microscopical examination showed a large number of granular and hyaline, and a few blood and epithelial casts, with a moderately large number of pelvic and tubule cells in a state of fatty degeneration. He was treated by lavage of the renal pelves twice a week and at the end of two weeks no casts could be found in the urine. The albumin had decreased to 50 per cent. by bulk—by Esbach's test was 5 gms. to the liter. The report of August 5 stated that there were no casts, very few pelvic and tubule cells and the albumin was 3½ gms. to the liter. From that date he was treated only once a week. On August 12 a few hyaline, granular and epithelial casts were found on both sides; albumin 3 gms. on the right, 4½ on the left. On August 19 there were no casts and the albumin had dropped to 2 gms. on both sides. He contracted a severe cold on August 27, and on September 2 the albumin was 5 gms. From then until September 28, when his treatment was discontinued, he usually showed a few granular casts and the albumin gradually dropped to 3 gms. When he came to me he was on a very restricted diet and was taking diuretin and nitroglycerin. I made no change in either the diet or medication. He has reported to me once a month since the lavages were discontinued and I have found that his condition still continues to improve. There has been a steady decrease in the amount of albumin and the casts are harder and harder to find. The patient tests his own urine every morning and finds that every time he takes salts that the albumin is markedly increased. He reports that the albumin varies from 2 per cent. to 10 per cent. by bulk, but when he takes salts it will jump up to 25 per cent. The last urinary examination that I made showed the albumin to be 1 gm. to the liter, and only six granular casts were found in looking over four slides. It is now nine months since he began treatment with me, and during that time he has lost only three days from work, when he was confined to the house last fall with a severe attack of bronchitis. He tells me that he is feeling better and stronger than he has at any time since August, 1903.

During the blizzard early in February he walked three miles through the snow to and from his work and said that it did not tire him at all. The case is a striking one, showing as it did from the very beginning of treatment by lavage improvement which cannot possibly be ascribed to anything but lavage of the renal pelves. It is not probable that he will ever be cured, but he has been put into such condition that he is able to work and support his family. He has been made comfortable and his life has undoubtedly been prolonged many years.

Case IV.—Typical case of parenchymatous nephritis, probably due to irritants circulating in the blood. Miss N., aged fifteen years; schoolgirl; came to the office September 14, 1904; gave the following history: In May, 1903, the morning after a hard game of basket-ball, she had quite severe pains in the lower part of the abdomen, radiating to the back, and had noticed that there was a large amount of blood in the urine. She was confined to her bed for two weeks, but just so soon as she was allowed to be on her feet again blood appeared in the urine. During the summer of 1903 she was taken to mineral springs in California and was kept on a milk diet and given medicine by the mouth, but the blood still persisted in her urine. She was kept in bed during September and October, 1903, and since that time a small amount of blood has occasionally been seen in the urine. Albumin was discovered soon after the blood was first seen and has persisted ever since. It has averaged from 5 to 10 per cent. by bulk.

When I first saw her the only symptoms complained of were an occasional dull headache with a general feeling of lassitude and weakness. There were no pains and no frequency of urination. No edema. No disturbance of vision. She was very anemic and appeared to be very weak. Pulse 95 and not increased in tension. Heart not increased in size and heart sounds normal. An Esbach's test showed 4 gms. albumin to the liter. Sp. gr., 1.014; brick-dust sediment; urea, urates and phosphates diminished. Microscopical examination showed a moderately large number of crystals of uric acid; few blood globules; few to moderate pus corpuscles; few to moderate number of epithelial cells from the renal tubules, the renal pelves, the ureter, the bladder and vagina. Few to moderate number of hyaline, granular, granular-fatty and epithelial casts. The patient was catheterized and treated by lavage of the renal pelves the following day. The report for the separate urines is practically the same as for the mixed, with the exception that there were no bladder nor vagina cells and the crystals of uric acid were absent. The inflammation was slightly more pronounced on the right side.

After the first and second treatments severe renal colics occurred, but thereafter no disagreeable symptoms manifested themselves. Very shortly after lavage was begun the number of casts became fewer and fewer. At times none could be found and then a few would be reported. The number of epithelial cells decreased to quite an extent and became more healthy in appearance. The albumin fluctuated markedly; at times being one-half gm. to the liter, then running up to 2 gms.

The patient was given a mixed diet: only veal, pork, the indigestible vegetables and all fried food being forbidden. She was attending school all through her treatment and was allowed to take moderate exercise in the open air, but never violent enough to sweat. The various modern uric acid solvents were tried, but without result. Old-fashioned rhubarb and soda, however, decreased the uric acid to quite an extent. Basham's mixture seemed to increase the albumin, so she was given tablets of iron, arsenic and strychnine with good results. She was treated three months and then sent to her home. The examination of her urine just before she left New York showed very few granular casts on both sides; very few tubule cells; moderate number of pelvic cells; few uric acid crystals; albumin three-quarters gm. to the liter. The patient's general health was markedly improved. Her mother, who had not seen her from the time she began treatment wrote me that she considered the change in her daughter's appearance little short of miraculous. The patient writes that she is now feeling twice as well as she ever did in her life. Owing to her youth she may entirely recover. She is now on a very restricted diet consisting of milk, well-cooked cereals, fish, white meat of poultry, clams and oysters. She is allowed lettuce, celery, asparagus, spinach and string beans. The report of the urinary examination made February 19, two months after treatment was discontinued, is: Albumin, one-thirtieth of 1 per cent; urea, 6 gr. to the ounce; sp. gr., 1.012; few crystals of uric acid; very few blood globules; few pus cells; few tubule cells; few cells from the renal pelves, bladder and vagina; no casts could be found.

I should have preferred to have kept this patient under treatment for one month longer, but it is my belief that she will continue to improve so long as she obeys instructions.

Case V.—Mr. B., aged forty-four years; manager; came to the office November 20, 1904. He had two attacks of urethritis twenty years ago. Each was quite severe and each lasted three months, but the patient thinks he was entirely cured. He had been perfectly well up to three months ago when he noticed he lacked the energy he formerly possessed and became easily tired. There was dyspnea on exertion. He had occasional numbness of the hands and feet; occasional headaches in the occipital region. Eyes would become blurred at times, and he often found great difficulty in reading unless there was a very strong light. Was extremely nervous and troubled by insomnia. No other symptoms.

Urinary Analysis.—Amount said to be 33 ounces; sp. gr., 1.022; urea, 330 grs.; urates phosphates and chlorides diminished; albumin, one-half gm. to the liter; crystals of uric acid, few to moderate; few pus corpuscles; few epithelial cells from the tubules of the kidney, renal pelves, ureters, and bladder; few to moderate number of hyaline and epithelial casts. He was very irregular in his treatment on account of business engagements and because of the extreme sensitiveness of the ureters, a proper lavage could not be given on the first two attempts. He has had only eight thorough lavages of the renal pelves, yet all his symptoms have disappeared. Even the eye symptoms have been relieved and he now reads as well as ever. The urinary analysis does not show so marked improvement as does the general condition. The albumin is now approximately 1 to 6 gms. to the liter. The uric acid still persists. The casts are fewer and occasionally entirely absent. The number of cells from the renal tubules, pelves and ureters have diminished slightly. I feel confident that if he were treated twice a week for about three months the inflammation in the kidney would be absolutely cured. He has not been restricted at all in his diet and the only medicine given was diuretin, which he had taken before without effect.

Case VI.—Typical case of interstitial nephritis, well advanced. P. J. N., aged thirty-two years; clerk. I saw him at his residence in consultation with Dr. C. E. Teeter. Part of my notes on this case have been mislaid so the past history cannot be given in detail. He had never had a venereal disease. His father died of gout about twelve years ago. The patient had been confined to his bed for three months and had been on milk diet and taking diuretin, nitroglycerin and strychnine. For three weeks he had vomited nearly everything he had taken by the mouth and was exceedingly weak. Pulse 94, and of very high tension. Heart considerably hypertrophied and second sound markedly accentuated. There was no edema. I advised against lavage of the renal pelves as not indicated in this case, but I performed it at the patient's request. The urinary analysis of the separate urines showed that both kidneys were affected equally. The albumin was 3½ gms. to the liter; urea, 4 grs. to the ounce; few to moderate blood globules; a few pus corpuscles; few granular casts; a very large number of epithelial cells from the renal pelves; moderate number from the renal tubules; few crystals of uric acid. Immediately after the first treatment the nausea entirely disappeared and he felt very much improved generally. He came to New York and was in the Post-Graduate Hospital for two weeks, receiving while there four lavages. Then he considered himself well enough to go home and come twice a week for treatment and he followed out this plan against my advice. The examination of the urine taken at the last treatment, while he was in the hospital, showed that the albumin had dropped to such a small amount that it could not be accurately measured by Esbach's test. The epithelial cells diminished considerably and no casts could be found.

On his first visit to the city after leaving the hospital he had an attack of heart failure and from that time he rapidly failed. I gave him two lavages at his home, but without result. He died late in November. This case will have to be put down as a failure, although the distressing symptom of nausea was at once relieved and he was generally improved at first. If he had been kept in bed all through his treatment perhaps the story would have been different. Yet he could never have shown the wonderful improvement that occurred in Case III.

Lavage of the renal pelves requires the utmost delicacy in handling the instruments and the injections through the ureteral catheters must be made with patience and gentleness. Asepis must be rigorously observed not only in regard to the cystoscope and catheters, but the hands of the operator and the urethra of the patient must also receive attention. The least roughness in the use of the cystoscope may cause injury to the urethra and vesical trigone. Lack of delicacy in the passage of the ureteral catheters may cause hemorrhage from ureters. The use of too strong or too irritating solutions may cause severe renal colic; and an injection that is too copious or given with too much force causes considerable pain and will not benefit the patient.

I consider the straight view cystoscope much preferable to the angular view in that it causes the patient much less pain; there is less danger of injury to the ureter; the character of any obstruction in the ureter may be more easily determined; and the entire operation of catheterization of the ureters is much more quickly completed with this form of instrument. Also I have been able to catheterize easily with the straight view cystoscope several patients on whom I had failed with the angular view. The instrument with which I have done most of my work is the one devised by F. Tilden Brown. I have had a modification of this instrument made so as to preserve its many valuable points and overcome its disagreeable features. With this modification it seems impossible for any one to injure the urethra or trigone.

The medication must be selected to suit each case. We often find one solution distinctly irritating while another is soothing. It not infrequently happens that a patient will be improved for a time by using one solution and then it will become necessary to change the form of injection to obtain the result desired.

The drugs that have been of more service in my hands in the treatment of nephritis by lavage are protargol, albargin, silver nitrate and argyrol. Protargol and albargin are used not stronger than one-quarter to one-half of 1 per

cent. Silver nitrate in a vehicle of boric acid is used 1 to 8,000, increasing slowly to 1 to 2,000. Argyrol, freshly dissolved, is used at 5 per cent.

Method of Lavage.—The time occupied in giving a lavage varies with different patients. Those who have a tolerance for solutions in the renal pelves require about fifteen minutes, while patients with irritable or sensitive ureters require half an hour. In the former cases the solution is thrown in slowly until there is a feeling of fulness over the kidneys; in the latter only about a dram should be thrown in at a time. In all about two to four ounces are used on each side. The injection should always be given at a temperature above that of the body—105° to 110° F. seems to be best borne by the patients. If the ureters are very sensitive the patient may, on the first injection, experience colicky pains, become nauseated and sweat profusely. If this occur it is best to remove the catheters immediately and postpone further lavage for at least one week.

A proper lavage of the renal pelves consists of repeated injections of small quantities of a medicated solution into the renal pelves through a catheter that has been passed well up the ureters toward the renal pelves. It is not necessary that the eye of the catheter be in the renal pelves, but it should be within six inches of it. After each injection the fluid is allowed to flow out through the catheter before a second injection is given. Never inject large quantities with the expectation that the fluid will run down the side of the catheter into the bladder. No one would distend the urinary bladder with the expectation that the fluid would flow out of the urethra by the vesical catheter. I have seen intense renal colics caused by the injection of only 1½ drams, and I have often wondered what would have happened had I injected more. As the catheter is withdrawn the solution is deposited all along the ureter so as to treat that organ. The patient is then requested to pass the water remaining in the bladder; a Janet wash of silver nitrate is given and the operation is completed. When I first began lavage of the renal pelves one of my patients developed a urethral fever after treatment. I have seen none since. In the early months also I had three cases of infection of the ureters from the catheters, but at present that is an unknown accident. The only disagreeable feature of this work at present is an occasional renal colic which may come on while the patient is on the table. Usually one-thirtieth gr. strychnine will relieve, but morphine is occasionally required.

In conclusion I wish to call your attention to the following points:

1. Not enough importance has been given to the probability that a large percentage of cases of chronic nephritis, in whom no discoverable cause for the inflammation can be found, are really due to extension of inflammation from the renal pelves.

2. Lavage of the renal pelves is only applicable in selected cases of nephritis.

3. Lavage of the renal pelves will certainly cure a beginning nephritis that is due to extension of inflammation from the renal pelves.

4. Lavage of the renal pelves in subchronic and chronic parenchymatous nephritis will check the disease and markedly improve the general condition of the patient, in those cases that have not reached the stage known as cirrhotic kidney.

5. Lavage of the renal pelves for nephritis by one who is not properly trained in the technic cannot possibly improve the condition of the kidney and may do harm.

616 Madison Avenue.

FETAL MANIFESTATIONS OF THE TOXEMIA OF PREGNANCY.[1]

BY WILLIAM S. STONE, M.D.,
OF NEW YORK;
INSTRUCTOR IN GYNECOLOGY, COLUMBIA UNIVERSITY.

IT was thought that in the consideration of the toxemia of pregnancy, it might be of interest to present some of the literature in regard to its occurrence in the fetus and to record the writer's own experiences.

The high mortality of the infant born of eclamptic women is attested by various observers. Bar, out of 80 cases of eclampsia, found that in 37 or 46 per cent., the fetus was dead born; 27 others died within the first three days after birth, and still others within a few weeks. He ascribes as a cause the high blood pressure that makes hemorrhages in the placenta. He also observed changes in the central nervous system, liver and kidneys.

In seventeen cases hemorrhages were noted in the meninges, liver and kidneys. Fatty degeneration was also present in the liver and kidneys, although less severe than in the maternal organs. He regards these manifestations as secondary and thinks they furnish evidence against the fetal origin of the disease. They may be, he says, of traumatic origin, rarely they are the result of infection, but are usually agonal and are not characteristic of eclampsia.

The number of cases of fetal toxemia recorded in the literature is small, and they have been regarded from two standpoints: First, as furnishing evidence that eclampsia is due to some poison generated in the mother and transmitted to the child; secondly, as offering another theory for the origin of the disease.

The transmissions of other toxins from the mother to the fetus, although an obscure chapter in placental physiology, has been sufficiently well demonstrated to lead us to believe that such may be the case in the toxemia of pregnancy.

Schmidlechner gives the causes of fetal death as due to: (1) high temperature; (2) disturbances of placental respiration from the changes of metabolism; (3) pathological changes in the

[1] Read as part of a Symposium on Toxemia of Pregnancy, at the New York Obstetric Society, November, 1904.

composition of the placental blood; (4) the transmission of infectious substances or other poisonous products. He cites a number of observations relative to the transmission of various toxins from the mother to the fetus. The demonstration of various gases in the fetal blood by Zweifel, Fehling and Porax; the presence chemically of chloroform in the fetal blood from a patient taking chloroform during labor; the demonstration by spectral analysis of coal gas in three children by Breslau and Freund; the salts of quinine by Runge and Porax, strychnine by Guinard, potassium iodide by Dührssen, and morphine by Peaslee and Thomas. He also notes the transmission of various infectious diseases from the mother to the fetus, such as typhoid, cholera, pyemia, septicemia and tuberculosis. Pregnancy, he says confers no immunity against infections, but typhoid and scarlet fever rarely occur, and cholera and smallpox are comparatively frequent, and their course is usually very severe. He considers the interruption of pregnancy to be due to the death of the fetus as pains rarely appear first. Sixty-three per cent. of typhoids abort, and the Widal reaction and cultures have been demonstrated in the fetal blood.

In cholera 54 per cent. abort. The vaccine virus, however, usually has no effect on the fetus, as, in mothers repeatedly vaccinated during pregnancy, subsequent vaccination of the child is almost always positive. Schmidlechner performed experiments upon nineteen pregnant animals with the diphtheria toxin and made the following conclusions: (1) A portion of the toxin is transmitted to the fetus and causes the same changes as in the maternal organs; (2) the intensity of the changes depends upon the quantity of toxin injected into the mother; (3) the changes develop quicker in the fetus and in higher grade than in the mother; (4) the path is through the placenta; (5) a very short time is required for the transmission; (6) most of the toxin in the fetal circulation remains for a long time unchanged, and the injection of this blood into another animal causes the same changes as were present in the first poisoned mother and fetus.

Bossi says that, except for diphtheria and its toxins, diseases in pregnancy are more acute, run a higher temperature, and are more fatal, frequently causing abortion, especially in the latter months, and that bacteria may be found in the placental and fetal blood in a number of cases.

The occurrence of convulsions in both twins born of an eclamptic mother, as recently reported by Brettauer, furnishes very satisfactory clinical evidence of the transmission of the eclamptic poison. Numerous other clinical observations have also been made. The presence of jaundice at birth in 56 infants out of 62 born of women who suffered from grave jaundice in pregnancy is reported by Lomer and is certainly suggestive, in the light of our present knowledge, of the toxemia of pregnancy. Cragin reports a case of an infant born of an eclamptic mother with general muscular contractures, but the possibility of intra-uterine rigor mortis in this and other conditions, as presented by Feis and Wolff, will demand careful histological examination before accepting such a case as a demonstration of the transmission of the eclamptic poison.

The presence of the disease in the fetus, as shown by post-mortem findings, is recorded in very few intances. Dienst, in 1902, reviewed and critically analyzed the cases recorded in the literature and also added his own experiences. They are as follows: Six cases of Schmorl, in which the autopsy in four showed severe degeneration of the liver and kidneys. Five autopsies of Lubarsch showing hemorrhages and necroses in the kidneys and thymus, slight in the liver. He considers them not to be agonal because of the presence of hyaline thrombi. One case of Prutz, in which the death occurred during labor, showed dilatation of the vessels of the kidneys and casts in the urine. A dead fetus removed by Cæsarean section by Gottschalk, showed epithelial necroses of the kidneys. Schmid found in a child that died from convulsions, superficial hemorrhages, cloudy swelling and miliary necroses in the liver and kidneys; casts were present in the urine.

Ebinger in five autopsies upon eclamptic children found in addition to ecchymoses of the pleura and pericardium and hyperemia of the liver, spleen and kidneys, cloudy swelling in the kidneys and heart muscle. Wilke, in one case of infantile convulsions, found an encephalitis.

Dührssen found a cerebral apoplexy in a child two days old that had had no convulsions. Dohm, in two dead fetuses removed by Cæsarean section found in one, epidural and subarachnoid hemorrhages, in the other marked venous congestion. Moraweck, in a case that had had ten convulsions, found, in addition to struma congenita and small pericardial hemorrhages, a very marked congestion of the liver, kidneys and spleen. Wendt found surface hemorrhages in different organs of a child born of a mother who had a severe albuminuria and jaundice without convulsions, but whose autopsy showed typical eclamptic changes. Knapp also found changes in the organ of a child similar to those in the mother. Dienst adds the clinical history and autopsy reports of two cases of his own, in which hyaline thrombi were found in the liver, lungs and kidneys. He also gives the result of the urinary examination in four infants, in which albumen casts and blood were found, the first time, he says, that the presence of blood has been noted in the child's urine in these cases.

Since this article of Dienst's, the writer has found a case, reported by De Lee, of eclampsia with convulsions in the child, but there is no description of the lesions with the report.

Bar and Daunay in 1903 found urobilin in the blood of an infant born of an eclamptic mother who had urobilin in the urine and blood. Very early in the present year, Dienst has added two cases to the literature. One was that of a woman,

who had suffered from toxemia for three months. An eclamptic seizure occurred during the labor, after which the fetal heart sounds ceased and the patient died in twenty hours. The maternal organs showed hypertrophy and dilatation of the heart with cloudy swelling and fatty degeneration of its parenchyma; the kidneys a chronic nephritis with acute degeneration; in the liver were fresh and hyaline thrombi. In the child's organs, the muscle striation of the heart was found to be obscure; the kidneys were the seat of cloudy swelling and fatty degeneration; there were also marked hemorrhages and edema. The urine showed red and white cells and casts; there was fatty degeneration with marked hemorrhages in the liver; in some places the cells were completely destroyed and the spaces filled with red cells; there were also red cells between the better preserved liver cells, and many recent thrombi were present in the central and interlobular veins. He considers these changes to be more recent than those in the maternal organs.

His second case he offers as anatomical proof of the course of the disease in both the mother and the child. A young primipara had been sick for two weeks, and while preparations were being made for the delivery, because of a dry labor and a weakened fetal heart, an eclamptic seizure occurred, followed in the next three hours by three others, after which recovery ensued. The child was born markedly asphyxiated and its first urine showed albumin, casts and leucin. Convulsions began in twenty-seven hours followed by jaundice and death. The autopsy showed punctate hemorrhages in the heart and pleura. The striation of the heart muscle were obscure and the cells showed cloudy swelling. There was fatty degeneration of the liver and in some places the cells were entirely destroyed; in the left lobe especially there were anemic and hemorrhagic necroses. He concludes especially from the finding of leucin in the child's urine, that an intra-uterine disease of the liver had existed.

These cases represent practically all that are recorded in the literature of the manifestations of fetal eclampsia. The writer wishes to add four others of his own:

Case I.—A young woman, single, eighteen years of age, had been suffering from amenorrhea, headaches, and a general feeling of malaise for several months, for which she had received large doses of iron. After returning home from a shopping tour she was suddenly seized with convulsions for which she was energetically treated for several hours on the assumption that they were of uremic origin, until the observation of the enlargement of the abdomen disclosed the fact that she was about seven months' pregnant. The cervix was undilated, and inasmuch as the patient's condition was somewhat improved, it was decided to rupture the membranes and wait until the cervix was sufficiently softened and dilated to perform extraction without injury to the maternal soft parts. A seven months' fetus was extracted the next day, which, although one or two repirations were noted during the extraction, was born dead.

The autopsy of the child, performed by Dr. James Ewing, showed the following: Body of a fairly well-developed seven-months' fetus; lungs collapsed; do not crepitate; heart normal. Liver of normal size, consistency moderately reduced. Glisson's capsule along anterior edge is stripped up by a fresh blood clot over an area 1½ cm. in circumference. Surface and cut section show uniform and intense congestion. Peritoneal cavity contains about 2 c.c. of clotted blood. Kidneys are both intensely congested; capsule and perirenal fat infiltrated with blood. Cortex shows minute hemorrhages. Both adrenals infiltrated with blood. Spleen normal.

Histology.—Liver. The liver cells show intense granular and hydropic degeneration, the cells consisting only of a shrunken nucleus, cell membrane and a few coarse cytoplasmic granules. There is little fat in the cells. Near the large hemorrhage the liver cells are destroyed by extravasated blood. There is no trace of bile in the liver cells or bile radicles, and no thrombi were found.

Kidneys.—There are numerous focal hemorrhages in the cortex and medulla, and marked general congestion. The cortical tubule cells show advanced granular degeneration. The other viscera show considerable congestion but no other noteworthy changes.

Case II.—Aged thirty-three years. VI-para. Previous history negative. Had been perfectly well during the pregnancy up to the day of her admission to the hospital. She stated that because of some contagious disease in the tenement where she lived she was obliged to walk the streets for three hours during the evening, becoming thoroughly chilled, and that when she found shelter and food, she overate, and in a few hours was seized with convulsions and brought to the hospital. Upon admission there was deep coma. General edema present. Marked urinary changes, but no leucin or tyrosin. After an intravenous infusion of 1,200 c.c. of salt solution, a modified Champetier de Ribes balloon was introduced into the cervix and saline irrigations of the colon were given for one-half hour every two hours. Uterine contractions began almost immediately and in six hours a seven months' fetus was normally delivered. The mother made an uneventful recovery. The child lived three days and had no convulsions.

Examination of the child's organs by Dr. Martha Wollstein showed the following: Lungs, pancreas, lymph-nodes and suprarenal capsules were markedly congested. *Liver.*—Its whole appearance is that of a fetal liver in which the lobules are indistinctly outlined. The intralobular capillaries between the columns of liver cells are distended with blood, and small hemorrhages have occurred, causing distortion of the columns with isolation of individual cells, which are nar-

rower than normal from compression. The interlobular septa are edematous and the veins are congested. The arteries are empty and the bile ducts are normal. There are no areas of necroses. Kidneys show marked congestion and in the intermediary layer there are some small hemorrhages.

Case III.—Aged thirty years. II-para. No previous history. Had had no convulsions for twenty-four hours before admission to the hospital. General edema; deep coma; urine contained large amount of albumin, casts and considerable blood. The pulse was 90, but of poor quality. Head upon the perineum. A seven months' dead fetus was rapidly extracted with the forceps. An intravenous infusion of 1,000 c.c. salt solution was given immediately, but before its completion an abortive convulsion occurred with marked cyanosis and the patient died. Post-mortem examination of the maternal and fetal organs, made by Dr. Martha Wollstein, showed the following: *Maternal.*—Heart muscle normal. Spleen intensely congested.

Uterus.—Placental tissue in the inner surface, syncytial cells being contained in the blood-vessels between the muscle cells just beneath the submucosa. These cells are in columns of 3 to 5 and do not fill any vessel. *Liver.*—Its cells show very marked granular degeneration, more so in some lobules than in others. Fatty degeneration has only just begun in some of the cells. The interlobular branches of the portal vein and the hepatic artery contain blood but are not distended. The intralobular capillaries are irregularly distended, causing pressure atrophy of many liver cells. The central veins are congested and the lobules are indistinct, several distended blood-vessels making up the center of the lobule. Hemorrhages have not generally occurred. Many leucocytes are collected within the congested vessels and there are a few outside. In some cases the entire lobule consists of dilated blood-vessels with very few liver cells left. Many lobules retain their normal conformation. When small hemorrhages have occurred, the liver cells at the periphery of the lobules show a marked hyaline degeneration, and the blood lies between the capillary walls and the liver cells. Fibrin thrombi are numerous and there is loose fibrin in the capillaries.

Fetal organs.—Liver.—Its cells have undergone a granular degeneration of the cytoplasm, amounting in some instances to complete necrosis; in others the nuclei remain intact and the cells have a transparent appearance. The capillaries and interlobular blood-vessels are congested. Small hemorrhages have occurred at the periphery of some lobules, by which the blood-cells are lying in and upon the liver cells, but have caused no pressure atrophy. *Kidneys.*—Degeneration in the epithelium of the tubules is very marked.

Case IV.—Aged twenty-five years. II-para. During the later months of the previous pregnancy, the patient had headache and trouble with her eyesight, which did not disappear until four weeks after the labor. Since then she has had no symptoms until about the sixth month of her present pregnancy, when headache and slight trouble with her eyes occurred and she noted edema of the face and legs. Upon admission to the hospital the edema was marked, especially about the face. The urine contained considerable albumin and casts; 11 grams of urea were passed in twenty-four hours. No leucin or tyrosin. Examination of the eyes showed a well-marked optic nerve atrophy, which was evidently the result of the previous pregnancy. Numerous hemorrhagic spots were noted in different parts of the body, appearing like bruises, and were possibly from that cause. In spite of rest in bed, fluid diet, and colonic irrigations, the symptoms, although improving slightly at first, became more marked in ten days, so that labor was induced by means of the modified Champetier de Ribes balloon, and a 6½ months' fetus was delivered, which lived twelve hours. The edema of the mother persisted for several days after delivery, but gradually subsided and she made a rapid recovery, although albumin and casts were still present in the urine at the time of discharge.

The post-mortem examination of the fetal organs, made by Dr. Martha Wollstein, showed the following: Edema of the hands and feet were present. Thymus gland contained many hemorrhages, the blood lying between the small sound cells, and in one instance filling about one-third of the lobule. Stomach showed congestion of the capillaries between the glands, and small hemorrhages were present upon the surface. *Spleen.*—Intense congestion and small hemorrhages into the pulp. *Liver.*—No hemorrhages were present, but there was marked congestion and hyaline masses were seen in some of the smaller blood vessels. The cytoplasm of the liver cells was granular with normal nuclei. There were no peripheral areas of necrosis, but columns of cells in many lobules were almost destroyed, having only a fringe of cytoplasm around the nucleus. *Kidneys.*—Showed intense congestion, and a few small hemorrhages were present between the tubules and into Bowman's capsule.

A comparative study of these lesions in the fetus must certainly establish their identity with those now recognized as associated with the effects of the eclamptic poison in the mother, as well as with those of other poisons. No uniform variation from the maternal lesions can be recognized in their distribution, although possibly they may be considered in general to be less intense than those in the mother. Marked congestion and hemorrhages may be more uniformly present in the fetus, but no more than is seen in some individual examples in the mother. Destruction and necrosis of the cells is, however, not so uniformly present, but Dienst's last case and the writer's first offer evidence of an ad-

vanced stage of the process in the case of the cells of the liver.

The prognosis for the fetus seems to depend, as Dienst says, more upon the length of time that the disease has existed than upon its intensity. The earlier in pregnancy, then, that disease begins, the less chance has the fetus for ultimate survival. In cases of short duration and severe intensity, although signs of asphyxia may be present, the child is frequently born alive. In cases of long duration, although comparatively mild for the mother, fetal death is more apt to occur, or if born alive, the child is apt subsequently to develop eclampsia and die, presenting at the autopsy changes in the organs, as in Case IV of the writer's, that would be considered severe in the mother.

The finding of leucin in the infantile urine of one of Dienst's cases is unique in the literature, and offers hope that a more uniform search for it in the maternal urine will furnish some guide to the clinician in the treatment of this important disease. It was absent in all of the cases reported by the writer, but in four other cases that had symptoms of a moderately severe toxemia without convulsions, it was found to be present. Dienst's opinion that it is evidence of an advanced pathological condition of the liver may or may not be true, as we have not any exact knowledge of how severe a lesion is compatible with recovery.

The fetus as an etiological factor in the disease has its advocates. The first suggestion that eclampsia may be of fetal origin is generally accredited to Fehling, in 1899, although Mouton writing in 1902 of the history of the fetal theory, says that Van der Höven first mentioned it in 1896. Christiani calls attention to the fact that Kollmann in 1896 first attempted to produce experimental evidence.

It is Dienst, however, who has most enthusiastically accepted this theory and from him we obtain fullest details regarding its occurrence.

The more frequent appearance of eclampsia in the latter months of pregnancy, its frequent occurrence in twin pregnancies, and the cessation of the symptoms after the death of the fetus, or its delivery, furnish evidence, he thinks, as to its fetal origin. He cites as further evidence a case of Kreutzmann, in which an eclamptic seizure occurred in a child thirty-six hours after labor, whose mother had had no convulsions. He also refers to Chamberlent who found the blood of a fetus more toxic than that of the mother. Dienst's interpretation of the fetal theory is that because of the disproportionate growth of the fetus at the end of the pregnancy some retrograde products of albuminous metabolism are found, which can only be transmitted to the mother through the placenta, as the fetal kidneys do not functionate.

These fetal poisons, even if they are small in quantity, are harmful to the maternal organism because they are delivered directly into the general circulation. If the elimination of these poisons is diminished by any insufficiency of the heart, liver or kidneys, they are retained, causing a degeneration and greater insufficiency of these organs, on account of which the liver is unable to complete its metabolism, and thus more toxicity will result. These poisons form a globulin in the blood and an increased formation of a ferment, which hastens the clotting of blood, causing thromboses and some of the necroses.

He does not think there can be any overproduction of poison in the child at the beginning of the disease, otherwise they would all die. While, then, he accepts the fetal origin of the disease, he considers the lesions in the fetal organs to be secondary to the poisons as developed and transmitted by the mother. As a certain time must elapse before the poisons become harmful to the fetus, it may happen in a very acute and severe form of the disease that the changes in the organs are very slight, analogous to the relatively slight changes that are found in the severest forms of peritoneal sepsis.

It may be said of this theory that fetal metabolism is probably a factor in the evolution of the disease in some cases, but the occasional occurrence of the gravest forms at a very early period of pregnancy would seem to make the possibility of the fetus as its origin incredible.

WHAT ADVICE SHOULD BE GIVEN TO WOMEN WITH MALPOSITIONS OF THE UTERUS?

BY CHARLES G. CHILD, JR., M.D.,
OF NEW YORK.

The frequency with which the above question arises, and the wide variance of opinion existing among specialists, as well as general practitioners, regarding the importance of uterine displacements, leads me to believe that a brief consideration of some of the more important aspects of this only too frequent condition will not prove lacking in interest.

The fact, long recognized, that in individual cases the previously normal uterus can lie in a retroposed position, without in any way disturbing the general balance of health, has led many to underestimate the significance of this condition as a causative factor of disease in a large, and unfortunately increasing, number of women. As a result many are dragging along through a tedious existence of ill health bordering on the verge of chronic invalidism, unfitted and unable properly to perform their social and marital duties, denied the saving and priceless boon of maternity, a burden to themselves, a disappointment to their family and friends and a sore trial to the poor martyred husband, whom the physician alone can understand. Truly a most pitiful social unit, deserving of our deepest sympathy and best endeavors in her behalf!

All cases of malpositions may be divided into two classes, the congenital and the acquired. As it is in the first that the most difficulty in advising is encountered, we will reserve it for a fuller consideration later.

The most marked, as well as the most serious, example of the acquired class is that of inversion, either partial or complete, and the indications for an immediate reduction so pronounced, that little time need be spent regarding the advice to be given the patient, save that the earlier appropriate measures for its relief are instituted, the greater will be the chance of obtaining a near approximation to the normal.

Of frequent occurrence is procidentia, also either partial or complete. Here there exists a hernia, not only of the uterus, bladder and appendages, but often of the omentum and small intestines as well, which, when allowed to persist, frequently gives rise to disease in widely removed structures, as a pyelitis or even a pyonephrosis by ascending infection from a chronic cystitis originating in the displaced bladder. As procidentia is progressive, usually proceeding from bad to worse, and the difficulty of effecting a cure increasing in direct proportion to the length of time it is allowed to develop, an early operation is attended with less danger and uncertainty of result, and the patient should be so advised, even though in the beginning her symptoms be slight.

The next acquired form probably most frequently encountered is the retroversion, or retroflexion occurring after a full term delivery, or miscarriage in the latter months of pregnancy, where a prompt replacement before adhesions have formed with the insertion and two to three months' use of a suitable pessary until the uterus and its ligaments have properly involuted is, as a rule, all that will be necessary. It is in these cases that the pessary has its greatest value, the retrodisplacement being readily corrected, and the necessity for an operation later thus avoided In the cases of adherent retropositions, accompanying disease of the appendages is the rule to which there are few exceptions, and any efforts toward replacing the uterus without proper treatment of the appendages should not be attempted. Here, however, effect is frequently mistaken for cause, and much time wasted in attempting to obtain an anatomical cure, which, however successful, will not result in a symptomatic one.

Hernia of the uterus through the abdominal wall, either at the medium line, or at the external ring, is of rare occurrence and usually calls for operative measures.

The lateral displacements are generally the result of disease in the adnexa, for which appropriate treatment should be instituted.

Anteflexion, so long considered a malposition, is now no longer regarded as such, but is due to a lack of development and does not concern us here, so that a passing mention will suffice.

This brings us to the congenital type, the varying clinical importance of which is so often underestimated. Caused by an error in embryonal development they are recognized by a short anterior vaginal wall, a long, thin cervix lying parallel to the axis of the vagina and close up under the symphysis pubis, and a small retroflexed, more often retroverted, fundus. Though generally free from adhesions they are not replaceable on account of the short anterior vaginal wall, that does not admit of the cervix swinging back into the hollow of the sacrum as the fundus is brought forward. A small proportion of these patients are free from physical symptoms and usually consult us for sterility.

What advice, then, should be given to women with these various malpositions? Let us consider for a moment the symptoms usually complained of. A sense of pelvic discomfort with more or less pain in the pelvis, back and the lower abdomen and thighs, aggravated by exertion, and worse at the menstrual period, accompanied by a more or less constant leucorrhea, progressive nervous manifestations and sterility, or the occurrence of frequent abortions in the early months of pregnancy, several, or many of which may be present in any one case. What degree of success can we reasonably hope to attain by the operative treatment of these symptoms? Some of them are very often the result of other pathological conditions not directly connected with the uterus, as the sense of pelvic discomfort complained of where the support of the pelvic diaphragm is lost as a result of exten-

sive lacerations, or even widely removed from it, as backaches consequent upon a displaced kidney. In the first instance repair of the perineum may accomplish a cure, but in the second any operation on the perineum or uterus would prove futile. The leucorrhea is seldom cured by operation and generally only yields to a more or less prolonged treatment by the application of caustics directly to the interior of the uterus and cervical canal.

Starting with the dictum that no case should be subjected to operative treatment merely to effect an anatomical cure, relieves us of a lenghty consideration of the uncomplicated retrodisplacements causing no physical symptoms. These in married women should be replaced and a cure attempted by the use of the pessary but should be a *noli me tangere* in the virgin.

In the adherent cases the result, as a rule, of pelvic peritonitis primarily involving the tubes and ovaries there will generally be found a marked train of symptoms increasing in severity, as the condition is a progressive one. Here operative treatment should be advised, though the occupation of the patient should be carefully considered before reaching a decision. Women of the leisure class who are not called upon to put forth any great or continuous physical exertion may be oftentimes readily relieved of their symptoms by office treatment, whereas women whose lives are more laborious, requiring them to be more or less constantly on their feet, receive little or no benefit from such means.

When the retrodisplacement is a congenital one the symptoms are not infrequently due to a lack of development in the pelvic organs rather than to the displacement *per se*, so that its operative correction is not always followed by a cure, although the symptoms may be much relieved, and if the patient is not too advanced in years, restoration to a normal position often results in a favorable further development. These cases being an error in development are seldom free from symptoms, and would in all probability derive the greatest benefit from an operation performed soon after puberty, but they do not generally come to our attention until later years when progressive suffering, or several years of unfruitful married life, leads them to seek the cause.

The most important symptom, from a social standpoint, and one for which we are so often consulted, is that of sterility, absolute or relative, and it is here that the greatest difficulty is at times encountered in deciding on what advice to be given the patient.

That the retroposed uterus, when not an absolute hindrance, can offer extreme difficulty to conception is true, and especially so in those cases where the cervix points forward toward the anterior vaginal wall. Here the mechanical obstruction to the entrance of the spermatozoa alone suggests an important causative element, and the accompanying state of venous congestion in the uterus offers a particularly unfavorable soil for the cultivation of a fertilized ovum. When conception does take place, abortion during the early months is of frequent occurrence, and this is especially true of those cases complicated by peritoneal adhesions, often so firm as to limit the excursion of the pregnant uterus to the pelvis, thus bringing on an early abortion by the inability of the uterus to enlarge sufficiently for the accommodation of its growing fruit. Where there are repeated abortions in the early months of pregnancy this condition will very often be found to be the cause, and an examination of the pelvic organs before the end of the second month is of extreme importance.

When the retroposed gravid uterus is uncomplicated by adhesions it should be replaced, and a retaining pessary worn until the fundus is well up out of the pelvis, and all danger of incarceration past. Where complicating adhesions make this impossible their operative separation with correction of the displacement should be advised as the only treatment consistent with good surgery and good morals; the interruption of the gestation by emptying the uterus, so often practised, is open to severe censure and need only be mentioned to be condemned.

When the retroposed pregnant uterus does not abort in the first few months—but continues to enlarge until the abnormally situated fundus becomes incarcerated under the promontory of the sacrum its immediate release should be accomplished, for the condition is a serious one which, when allowed to persist, always results in the death of the fetus and is often attended by disastrous results to the patient; vesical complications, especially gangrenous or membranous cystitis leading to death are of not uncommon occurrence.

The conclusions that I wish to draw then, from this necessarily limited consideration of the subject, may be summarized as follows:

I would divide all malpositions of the uterus into three classes: Operative, non-operative and questionable.

The operative class may be further divided into those requiring immediate attention, and those in which it is safe to await for a reasonable time the convenience of the patient. Under the first subdivision come those cases which may be classed as emergency ones, namely—inversion, incarceration and irreducable prolapse of the gravid uterus, and adherent gravid retrodisplacements with symptoms of threatened abortion. In the second subdivision are the complicated retrodisplacements, and hernia of the uterus either through the vagina or through the abdominal wall. In the non-operative class I would include the uncomplicated retrodisplacements, and reducible hernia of the gravid uterus.

The questionable class embraces the congenital type of cases, and retrodisplacements with

symptoms relieved by reduction, but where the use of a proper pessary fails to accomplish an anatomical cure, or in young virgins where its use is unjustifiable. The congenital cases being errors in development are each a law unto themselves, and require a most thorough investigation.

Where the retrodisplacement is the only abnormality present, the patient is often greatly benefited by an early operation, but where other marked evidences of maldevelopment exist the prognosis is unfavorable.

61 West Forty-Fifth Street.

CARBOLIC ACID GANGRENE.

BY JUSTIN HEROLD, A.M. M.D.,
OF NEW YORK.

THE peculiar integumental changes which occasionally manifest themselves in certain cases after exposure to the action, externally, of even mildly diluted solutions of carbolic acid, have prompted many surgeons to discard its use in surgical practice, excepting for the immersion of instruments which, as is known, are tarnished when placed in a solution of the bichloride of mercury. The public, and unhappily many pharmacists and practitioners of medicine, do not appreciate thoroughly the grave dangers residing in the daily and popular use of carbolic acid solutions as a routine application to open wounds and injuries of other character. Injuries to the fingers and toes, trifling in extent, to which carbolic acid in various strengths of solution is applied too freely, in some cases, have resulted in gangrene of the parts to which the acid is applied. In this connection, gangrene due to injury, calling for the use of carbolic acid, is excluded. As remote as 1871, Tillaux (*Bull. Gen. de Therap. Med.*, etc., Vol. LXXXI, p. 275) reported three cases of carbolic acid gangrene, and since that time writers in various countries have at frequent intervals reported similar cases. Theodore Billroth, some years later, in a letter published at Vienna, cautioned against the too indiscriminate use of this irritant, and said that he had at that time seen four cases in which the fingers, which had suffered a most insignificant injury, became gangrenous through the uncalled for external application of carbolic acid. These results are due to the unfortunate popularity that carbolic acid has attained in the public mind as an antiseptic for the treatment of wounds, and also to the faith which physicians and pharmacists place in its omnipotence. In the face of all this, the misuse of carbolic acid continues, and it is with the object of attracting further notice to this deplorable and indiscriminating use of a toxic agent, that the author desires to add to an already long list a case of carbolic acid gangrene which came to his notice recently.

Case.—Mr. George T., aged thirty years; by occupation a laborer in a coal yard; family and personal history negative. Addiction to beer-drinking to a slight extent only habit. While at work, "scraped" end of middle finger of right hand on a sharp-pointed nail, bled freely, necessitating bandaging. Consulted his physician, who ordered a two-per-cent. solution of carbolic acid, to be diluted with an equal quantity of water, and then wrapped around finger. Patient did as directed, keeping the bandage around the parts well-soaked with the solution. On removing the dressings twenty-two hours thereafter, finger was found to be discolored and shriveled as far in extent as the bandage reached, bandage was loosely applied, no constriction at any point. Case was referred to me for further treatment, in conjunction with family physician. Patient had faithfully applied the one per cent. solution of carbolic acid, to parts as far as the solution of integument can be noted in the accompanying illustrations. Urinary examination showed absolutely normal constituents; no sugar, no albumin, no casts, sp. gr., 1.018; quantity in forty-eight hours, 44 ounces. With the assistance of the family physician, amputation at the middle of the first phalanx was performed, under ether. The anteroposterior flaps united perfectly in ten days. Illustrations show perfectly the extent of the gangrene, on palmar and dorsal surfaces of finger.

Francis B. Harrington, visiting surgeon to the Massachusetts General Hospital, in an excellent article published in the *American Journal of the Medical Sciences* for July, 1900, reviews the entire subject of carbolic acid gangrene as presented up to that date, and adds 18 cases, which he has discovered or seen through others at the Massachusetts General Hospital, to 114 cases, the reports of which he found in the medical literature of various countries. He appends a list of bibliography on the subject covering sixty monographs appearing in the literature up to that date. Since the publication of Harrington's paper, many isolated cases have been reported by Lucas-Championniere, Bindi, Romeick, Vertner Kenerson, E. Dunster Kremers and George E. Shoemaker. There are, however, many cases which are not recognized as carbolic acid gangrene, and these, with many recognized cases, are never reported. The lenient restrictions governing the selling of carbolic acid, in retail or bulk (in great part, corrected by recent legislation), the ambiguous instructions as to its proper employment, and the ignorance on the part of the public in general as to the dangers lurking in its indiscreet use, are responsible for the seemingly too frequent occurrence of carbolic acid gangrene. The external application of carbolic acid has also produced severe constitutional disturbances and has even destroyed life. This is due to the fact that carbolic acid possesses real penetrating power, a fact evidenced by the numerous cases of constitutional poisoning reported at various times. The continual use of the solution may and does give rise to headache, vertigo, fainting, vomiting, ir-

regular breathing, and a thready pulse.[1] One of the first symptoms of carbolic acid poisoning is the characteristic olive-green coloring of the urine, when the acid is applied externally, later the urine may respond to the albumin tests, and carbolic acid be even recovered from the same by analysis. In severe cases there are bloody diarrhea, hemoglobinuria, suppression of urine, contracted pupils, clonic muscular spasms, and collapse leading to a fatal termination. Individual disposition probably plays a part. Infants and young children are especially susceptible to the toxic action of the drug. Very distressing and alarming constitutional symptoms, and even death, have followed the application of a mild solution to minor wounds, such as the wound of circumcision. It is foreign to the purpose of this article to take up this phase of

Fig. 1.

Carbolic acid gangrene. Dorsal surface of finger.

the subject, but we shall review the question of disturbances as a result of the local action of carbolic acid, *i.e.*, mortification or gangrene.

Experiments have proven that the use of the full strength of the acid is not necessary to produce gangrene. Indeed, Joseph Levai (*Pest. med. chir. Presse*, Budap., 1897; *Ungar. med. Presse*, Budap. 1897, has shown that strong carbolic acid is less dangerous, for it forms a scab which restricts penetration of the irritant drug into the deeper tissues. When applied to the skin, the superficial layer of tissue is coagulated and thus absorption of the drug is prevented. It produces great local anesthesia, extending inward for some depth, to the tissues with which the acid has not come in contact. This superficial slough is cast off, and thus complete mortification is less likely to occur under these circumstances than when dilute solutions of the acid are employed. As Harrington says, the result depends on the strength of the solution, the manner of application, the length of time of application and the power of resistance of the individual. However, it is probable that the strength of the solution has less do do with the unfortunate result than the length of time of the application and the thickness of the epidermis. It is worthy of comment that in Harrington's cases women made up four-fifths of the total number. It is needless to state that mortification does not always follow the use of carbolic acid solution as a wet dressing.

The local toxic effect of carbolic acid has been studied in a very exact manner by a number of writers, among them, Prudden, Körtum, Frankenburger, Lucas-Championniere, Levai and Housel. Prudden (*Am. Jour. Med. Sciences*, January 1881) "observed under the microscope the effect upon living leucocytes and ciliated cells, of soakage in varying solutions of carbolic acid. Under soakage in solutions between $^1/_{32}$ per cent. and $^1/_4$ per cent. strengths, ameboid and ciliary movements slow up, or stop, but resume activity upon withdrawal of the carbolic fluid and its replacement by a normal one. Under soakage in solutions of one to five per cent., however, the bodies under observation speedily lose their power of movement, without possibility of resumption, and their protoplasm soon suffers disintegration. Applied to the human skin, comparatively weak solutions, such as one to two per cent. solution used in surgery, objectively cause a whitening and shriveling of the cuticle, and subjectively a conjoint numbness and prickly sensation, followed, if the application be prolonged beyond a few minutes, by smarting. These painful sensations Squibb declares to be aggravated by elevating, and alleviated by depressing the affected part,—phenomena contrary to those which usually obtain under circumstances of painful irritation. After withdrawal of the application the skin gradually assumes its normal appearance and tactile sensibility, recovery from the numbness, however, being slower than the return to natural appearance. Touched with the undiluted acid, the skin immediately whitens, while the circumjacent parts redden by irritation. Sharp pain, passing over into numbness, is experienced, the pain gradually subsiding after an hour's lapse, and the surface presenting the dry, scaly exudation so often seen on surgeons' hands in the days when operating under a carbolized spray was in vogue" (Reference Handb. of the Med. Sc., Vol. II).

Körtum (*Intern. klin. Rundschau*, No. 52, 1888) attempts to explain the gangrene resulting from the continuous application of carbolic acid solution on the ground, first, that carbolic acid has a toxic effect on the nerves, and secondly, that a watery solution of the acid is easily absorbed by the tissues, and then exerts its familiar property of coagulating albumin. The

1 Herold's Legal Medicine, J. B. Lippincott Co.

chemical first irritates, then paralyzes the vasomotor nerves, and it may exercise the same effect on the sensitive and trophic nerves, for there is at first, upon applying the acid, an acute smarting and burning sensation, followed later by anesthesia. He believes that it is very probable that the trophic nerve disturbances play an important part in the production of gangrene. As has already been stated, watery solutions of the acid are easily absorbed and penetrate deeply into the tissues. The property of coagulation of albumin by the acid also plays a part in the causation of mortification. Under favorable circumstances there is a paralysis of the vasomotor nerves, and a consequent slowing of the blood current.

Frankenburger's (quoted by Harrington) explanation is worthy of consideration. In 1890, he conducted a number of experiments upon

Fig. 2.

Carbolic acid gangrene. Palmar surface of finger.

animals, and proved that dilute carbolic acid solutions would produce complete destruction of the parts to which they were applied. The subcutaneous tissue showed considerable transudation. From these studies, he concluded that the chemical acted directly upon the red and white blood corpuscles, causing stasis and thrombosis. This in turn prevents nutrition and thus produces death of the part. He believed that the local effect upon the nerves was of minor consideration.

Levai (*Gyo-gyszat.*, Budap., 1897, Vol. XXXVII, pp. 75 to 94; *Pest. med. chir. Presse*, Budap., 1897, Vol. XXXIII, pp. 177 to 183; *Ungar. med. Presse*, Budap., 1897, Vol. II, p. 172) doubts the conclusions of Körtum and of Frankenburger. His experiments make it seem probable that the action of carbolic acid is not a specific one, but is analogous to that produced by 5 per cent. solutions of hydrochloric, nitric, sulphuric and acetic acids and of caustic potash when applied to a part by means of a saturated compress for about twenty-four hours. He showed by histological examination that in the beginning, each of the above chemicals properly diluted and applied in the form of moistened compresses, produces the same effect: the epithelial layer becomes edematous and loosened. "As soon as a way has been made to the deeper layers, each agent produces in a different way the same result, namely necrosis of the living tissue." This mortification takes place in layers downward, and exercises its effect not only on the nerves and vessels, but involves all the tissues of the watery solution on the skin causes its ultimate maceration, and thus penetration of the chemical becomes easy and rapid.

Championniere says that in the cases observed by him the damage usually took place in localities where the circulation has always been feeble. He attributes the destruction to the toxic effect of the acid on the cutaneous nerves causing a trophoneurosis,—an impaired nutrition due to defective nerve influence.

As has already been stated, clinical observations prove that it is the mild solutions of carbolic acid which are the more dangerous, since they cause no pain and in consequence their effect is a decidedly more insidious one. Peraire (*Jour. d'Anat. de Paris*, February 5, 1896) records an instance in which a child ten years of age lost the second and third joints of a finger after twenty-four hours of exposures to a compress saturated with a one per cent. solution of carbolic acid. Levai reports a case where gangrene followed the application of a two per cent. solution for twelve hours. In some cases, mortification has resulted in three or four hours where the solution was in a more concentrated form. Thus Körtum (*Inter. klin. Rundschau*, No. 52, 1888) records such an instance in which the last phalanx of the thumb was destroyed after a single application of an eight per cent. solution. He reports other cases where one or two per cent. solutions produced gangrene, and further speaks of an interesting case where multiple spots of gangrene appeared in the hand after the application of compresses moistened with a two per cent. solution of carbolic acid and applied for several hours. Vertner Kenerson (*New York and Phila. Med. Jour.*, February 4, 1905) reports a case where the solution, at first, was 1 in 50, and then later changed to 1 in 100. In this instance, the wet dressing was covered with oil silk. A patient was ordered to apply a two per cent. solution of carbolic acid for four hours for the purpose of aborting a felon, and was instructed to remove the dressing as soon as the skin was blanched. About five hours later, the finger was reported as blanched, but "pricking stone." Orders were then given to

reduce the strength of the solution to 1 to 100, *i.e.*, one per cent. About this time a friend of the patient suggested covering the wet dressing with oil silk, which was done without consulting the physician. The application was left *in situ* over night. The following day parts of the finger were dusky, and while attempts were made to care for return circulation by placing the finger in a warm poultice (to some extent, it did improve in the proximal joint), dry gangrene followed and it became necessary to amputate at the tip of the first phalangeal bone. Kenerson concludes his report by saying: "Carbolic acid is the best penetrating disinfectant in those infections that do not proceed from an open wound, as it has real penetrating power through unbroken skin, but it should never be covered with any material that will prevent evaporation, and should be applied only with a light dressing."

E. Dunster Kremers (*Jour. Am. Med. Ass'n*, August 27, 1904), Lucas-Championniere (*Rev. gen. de clin. et de therap.*, Paris, 1903), F. Bindi (*Clin. med.*, Pisa, 1903, IX, pp. 103 to 105), Romeick (*Zeitschr. f. med. Beamte*, Berl., 1903, XVI, p. 124), George E. Shoemaker (*Am. Med.*, July 9, 1904), Du Castil and Nocton, "Gangrène du mamelon d'origin probablement phèniquée." *Bull. Soc. franc. de dermat. et syph.*, Paris, 1904, XV, 28, are among those who reported cases since the publication of Harrington's paper. The records of all these cases are so much alike that a detailed report of each would be a needless repetition.

Experiment has shown that the gangrene is not due to tight bandaging or to compression, but simply to the action of the carbolic acid. Tight bandaging undoubtedly encourages the tendency to this retrograde process, but clinical experiences have shown that the gangrene does not develop primarily from this cause. The gangrene is limited to the tissue enveloped by the moist compress, and is determined by a sharp line of demarcation, as is shown in the illustrations accompanying this article. This has been demonstrated by a case of Levai, where the last phalanx of a finger, which was not covered by the dressing, escaped the gangrenous process and presented a normal appearance and bled when pricked with a pin; the finger nearer the trunk was quite black and without sensation.

In cases of carbolic acid gangrene, the history, as a rule, is as follows: The patient usually comes for treatment with the history of having treated a cut, bruise or a felon with a solution of carbolic acid or with an ointment containing small quantities of the drug. It is reasonable to assume that solutions of carbolic acid usually are no stronger than five per cent., since water, which is the usual solvent, will practically only dissolve about five per cent.[1] Hence, most cases of gangrene due to this acid, result from the application of solutions varying in strength from one to five per cent. (one per cent. in my case, here quoted). The story reveals the unfortunate error of many druggists, when selling the acid without a physician's prescription, in not sufficiently cautioning the customer regarding the danger of the continuous application of the drug. It may be a physician, unhappily, who is found culpably derelict in his duty in a matter of this kind.

Carbolic acid, either in the form of a dilute solution or of an ointment, is the agent that occurs to the mind of most people as the proper remedy for use as an antiseptic. This, and the want of knowledge as to its judicious use, is the reason for the frequent occurrence of carbolic acid gangrene. Upon examining the affected member it will be found dead black in color, somewhat shrunken, devoid of sensation and dry. A sharp line of demarcation is established, and there is no odor. Hopeless disorganization is readily recognized, and the only therapeutical measures at our disposal are amputation or disarticulation. An alcoholic dressing may be tried, with the hope that it may destroy any carbolic acid remaining in the surrounding partially dead tissue. It might be beneficial to apply a dressing saturated with lime water, if the case is seen soon after the removal of the carbolic acid.

Prophylaxis.—Lucas-Championnière advises the use of glycerin in combination with carbolic acid rather than the usual aqueous or alcoholic solutions. The best prophylactic consists in the avoidance of the use of this chemical for wounds, and to resort, in its stead, to some of the many other excellent drugs for this purpose. The very best, according to the *International Journal of Surgery*, is a lotion known under the name of Burow's solution, which is easily prepared by dissolving 28 grains of lead acetate crystals in water, pouring this solution into a vessel containing a solution of 70 grains of alum, and then diluting up to 800 grams. The resulting precipitate of lead sulphate must be thoroughly filtered out. This may be further diluted when required for moist compresses, the latter being well covered with rubber tissue or oil silk to prevent evaporation. "Although such unfortunate results (referring to Dr. Harrington's paper in *Am. Jour. Med. Sciences*, Vol. CXX, p. 1) from the external application of carbolic acid have been known for many years past, it needed just such awakening as this paper furnished to call attention to the results of too recklessly using this valuable agent. It is well known, however, that gangrene does not invariably follow from such applications, but this fact shall not deter those who have occasion to recommend or actually make use of such solutions from advising caution, and especially to keep it out of the reach of children. The general consideration which has been given to this subject has developed the fact that many surgeons cannot quite agree with Dr. Harrington's general advice to use the other substitutes for wet dress-

[1] Herold's Legal Medicine, J. B. Lippincott Co.

ings, for the beneficial results have been marked in too many cases with carbolic acid solution. They would rather call for more care in its use."

325 East Eighty-seventh Street.

THE MEDICAL PROFESSION IN ITS RELATION TO THE ELIMINATION OF COMMUNICABLE DISEASES.[1]

BY EDWARD N. LIELL, M.D.,
OF JACKSONVILLE, FLA.;
PRESIDENT FLORIDA MEDICAL ASSOCIATION.

EVERY thought has a literal value. In the degree that thought is focussed and given direction is it effective in the work it is sent out to accomplish. We should not fail to realize that however small our contribution, its impulse may be felt far and near.

Those of us who, from year to year are honored, through this high office, in being chosen to speak to our fellow practitioners, must be regarded mainly as torch-bearers, receiving light from those whose torches have burned brightly, and placing a still larger flame in the hands of our successors. Every act of a physician's life inscribes itself in the memory of his fellows. He must be a light to illume, to be prepared to scatter sunshine where clouds and shadows reign.

The conscientious physician is attached to just principles and governed by the highest motives in doing good. His work is never ending, and his patience inexhaustible. Moreover, he owes allegiance primarily to the general welfare of the community and to moral and intellectual convictions. It is heredity to devote whatever talents may be his to safeguarding the public health and to advance the best interests of his profession. To learn the truth with him is to proclaim it. To this spirit of self-sacrifice and scientific zeal devoted to humanity there is no parallel.

There is a spirit of inquiry, a thirst for knowledge, pervading our profession, and speculation is displaced by fact. One of the most important elements of success in life, and even of happiness, is a trained habit of observation: the power of accurately noting and comparing. Invaluable discoveries have been made by simply observing and reflecting on what was going on under one's eyes. Observation and research are prime factors in the wonderful advance and revolutionary changes constantly going on. Theories advanced by one are overthrown by another unless they stand the crucial test of successful repetition. As science is so abundantly demonstrating to-day, the things which we see are but a small fraction of the things that are. The real vital forces at work in the world about us are not seen by the ordinary physical eye.

There are two classes of workers in the profession of medicine,—those engaged in the discovery and those engaged in the practical application of scientific truths. Both of these realize the immensity of the field, the danger of propagating error, the gradual development and practical application of medical knowledge, and the agony of an argument with ignorance, prejudice and superstition.

Prophylaxis, the science of the preservation of health or the prevention of disease, is based upon our knowledge of the causation of disease. To prevent the latter, one must first grasp somewhat of its nature and origin. What has been accomplished in this direction within the past quarter of a century far transcends the wildest speculation of the theorist of but half a century ago. During this period, medical science has turned empiric chaos into scientific order. A complete revolution has been brought about through bacteriology, and renewed zeal has been awakened in various directions to curtail or prevent disease and thus tend to increase the average duration of life.

To acquaint laymen with the aims and possibilities of the medical profession in relation to preventive and sanitary measures is a problem of gradual solution. There is a natural conservatism possessing the human mind, which makes it slow to grasp the import of revolutionary facts. Until the public is educated through us to understand its importance and possibilities, and necessary laws enacted and enforced, preventive medicine will never be accorded its proper place as a scientific branch of medicine. The slow working of natural laws tends to bring about reforms in all things, but it should be the accepted duty of every intelligent citizen to endeavor to assist in educating the masses. The public as well as our patients should be taught the nature of infection and contagion as applied to various diseases, and they should be persuaded to observe ordinary sanitary precautions. Where the will fails the law should step in.

Any measure which will preserve the resisting power of the individual against disease is essentially based upon as sound a principle of prevention as that which, for the same reason, endeavors to keep disease away from the individual by preventing him coming in contact with cases of that particular affection. Even the seeming miracles of modern surgery are due as much to the knowledge of the means by which inflammation and suppuration may be prevented as to the skill of the operator.

Disease expresses the reaction of the organism, not the action of the germ; the germ is no more important than the tissue it invades. Whatever the character or proportion of infective or contagious diseases existing, the danger in a community is directly proportional to the number of cases existing. The more perfect the intimacy the greater the risk, the more frequent the infection. There is at present a strong belief that most epidemics of the various infective diseases are spread by mild cases which go unrecognized, rather than by the mediation of a third party.

[1] Address delivered at the thirty-second Annual Meeting of the Florida Medical Association, held at Jacksonville, April 19, 20, and 21, 1905.

We are to-day in possession of a satisfactory working theory of the nature of infective disease, and of the factors involved in natural resistance and acquired immunity. Our wonder knows no bounds regarding these, so marvelous is the precision and scope of the protective reactions, concerning which so much has been brought to light in recent years and which lend themselves well to comparative studies. In natural immunity, there exists in certain families or species an inborn resistance to certain infective germs. The reactions of natural immunity, however, may not neutralize quickly enough the toxins nor destroy promptly enough the invading organisms Hence the intervention of products of artificially produced biologic reactions. Yet methods of artificial immunization will never enable us to dispense with the observance of general and proper hygienic precautions, which increase the resistance of the tissues.

When success attended the production of specific antitoxins for diphtheria and tetanus an important step was taken in serum therapy and immunization. Yet the failures that have been met with in the attempts to produce antitoxins for other diseases have only stimulated investigators the more to a closer study of immunity and of the means by which bacteria cause disease.

The greatest medical triumphs have been won in the realm of the infinitesimal beings that, unseen, swarm and multiply within and about us. Bacteriology was born of philosophic doubt as to spontaneous generation. It has furnished a solid basis for preventive medicine, capable of conferring more and more benefits on mankind as its principles receive wider application. The spirit of research has become so diffused as to penetrate into almost every department of human knowledge and activity. With a recognition of its usefulness and its necessity as an element of progress, bacteriologic research is proving an indispensable factor in the study of those important problems in medical science so intimately associated with the health and happiness of mankind.

The laboratory has, in fact, become indispensable in the daily life of the progressive physician, technical and positive aid being thus offered us in individual and general diagnosis, through bacteriologic and chemical examination. The laboratory gives facts, and it rests with the clinician to interpret them. We have now, in this country, various institutions promoting individual research toward advancing the science of medicine; such are the United States Marine Hospital Service Laboratory, the Carnegie Institution, the Rockefeller Institute, the Memorial Institute for Infectious Diseases, and the William Pepper Laboratory of Clinical Medicine. To these may be added the Harvard University Department of Research, and the Bacteriological Laboratory of the New York City Board of Health.

No field for medical research is more promising for investigation than that of the composition and chemistry of the blood. Within the past few years much attention has been given to it, and in at least a half dozen diseases does a diagnosis rest entirely on the blood examination. In the establishment of a bacteriological laboratory, our efficient health officer and our active and enterprising State Board of Health have taken advantage of the necessities arising in connection with its sanitary work. The advantages which the laboratory holds out, moreover, to every member of the medical profession, through the generous and gratuitous privileges of the board, cannot but commend itself to every one of us. It is pleasing to note the steady growth, the influence and increasing confidence in the laboratory and its findings, and it is with commendation that I refer you to the instructive annual report of the bacteriologist, and in addition, of the State Board of Health. The physicians throughout the State, more especially those of the larger cities and towns, now generally avail themselves of the proffered opportunities tending to a positive or negative diagnosis, through bacteriologic or pathologic examination.

The perfection of bacteriological methods in relation to typhoid fever, that of cultivating the bacilli from the blood, urine and stools, and the Widal reaction,—these have made possible the induction of a positive diagnosis within the first week or ten days usually. The lightness with which gonorrhea, a disease so prevalent, so contagious and so fraught with dangers to both sexes, is viewed by the public is most singular. The idea that public interests will be furthered by a recognition of the dangers of gonorrhea, is, as yet, an unfamiliar thought to the laity. Yet it is only within recent years that they, through repeated warnings of medical men, have become aware of the perils of tuberculosis. Regarding the latter, the greatest scourge of the human race, which is tolerated and engages general sympathy, the fatal sense of the lack of need or uselessness to combat the contiguity risk still seems to dominate many families in which such disease has made its appearance. The experience tables of life insurance companies, which are the only safe and reliable guides, based on many thousands of consumptive deaths resulting in claims for insurance, show that the families tainted with tuberculosis furnish, up to the age of forty, nearly 50 per cent. more deaths than families not so tainted. Life insurance companies therefore should, in my opinion, take an active and serious interest in preventive medicine, in that they profit by every advance in medical discovery and progress. The activity of boards of health in educating the masses as regards the real character of tuberculosis, has not only brought the disease more and more under control, but has markedly decreased the death-rate, the greatest decrease being shown by New York City, as a result of active administrative control through the energetic

efforts of its enlightened board of health. There should be established in Florida, in one or more favorably situated country districts, available sanitaria, under the supervision and control of the board of health, for the care of early and incipient cases of tuberculosis. Such care not only removes the individual as a source of danger to others, but also affords the best chance for recovery.

And now a word as to schools, in relation to communicable diseases. It is undeniable that the school is a patent factor in the propagation of disease, and under many conditions found, a train of physical ills are consequent that seem to be the price the child must pay for its education. School children are of a susceptible age, and wherever a number of children are brought into close contact the dangers of dissemination of communicable diseases is materially increased. While it is impossible entirely to eliminate all diseases from the school, yet its decided mitigation is entirely within reach. A systematic daily medical examination is a demand made by the modern recognition of preventive medicine, and its full significance is becoming more widely appreciated as its results become more apparent.

The subject is one of no limited extent. Every individual, physician or layman, should take an interest in anything tending to aid in preventing sickness or in avoiding contact with another having a communicable disease. The State should realize also that health is a condition of citizenship, and protection of the health of its child population implies a better class of citizens for the future. Health officers cannot rise far above the standard of culture of those who provide the means for administering the law. By improvement of our public health service will the communities in general receive the benefits to which they are entitled by virtue of our advancing knowledge as to the origin and transmission of disease.

MEDICAL PROGRESS.

MEDICINE.

Cancer of the Uterus.—J. A. SAMPSON (*Journal A. M. A.*, May 20) takes up the subject of uterine cancer, more especially that of the cervix, with special reference to the importance of early diagnosis and treatment. It is of importance to the medical profession, first on account of its frequency, it being the most frequent primary form of the disease; second, because it occurs mostly in middle life; and third, because of the distress and suffering it produces. With an early diagnosis a large percentage of cures is possible, but on account of ignorance and neglect most operable cases pass into the incurable stage. Hence the importance of educating physicians, and through them the public, as to the curability and the diagnostic points for its early recognition. One early symptom easily recognized is bleeding, sometimes profuse, sometimes slight, but always abnormal, and therefore likely to attract attention. In the rare cases in which it is absent, other signs usually exist that should lead to the suspicion that there is something wrong and needing investigation. Few patients unoperated on live over three years after the appearance of this symptom, and the majority die within one or two years. An absolute prognosis can not always be made either before or after operation or from examination of the specimens removed. With present methods, recurrence is likely to take place in three-fourths of the cases operated on, but operation may still be useful as a palliative, relieving suffering and lengthening life. Although he reports here a case of apparent cure of recurrent cervical cancer, Sampson is doubtful as to the propriety of operation in cases of recurrence. The value of education in this matter is shown by the experience of the Johns Hopkins Hospital. There has been a steady increase of the proportion of early diagnosed and operable cases and of the percentage of cures, and this increase has been most noticeable among the educated and well-to-do women. Sampson refers to Winter's campaign of education in Prussia, by which the operability of uterine cancer was increased in East Prussia from sixty-two to seventy-four per cent. in one year. The need of a more radical operation in these cases is pointed out, especially in patients in good general condition, with a freely movable uterus apparently in the early stages of the disease. When the growth is apparently extensive and its removal difficult and the patient is in poor condition, unless a very thorough operation can be done, including even excision of the lower portion of the ureters and part of the bladder, taking in all the diseased tissue, he advises that nothing be attempted. In very extensive inoperable cases he would treat the symptoms and do as little as possible locally. The article concludes with some remarks on cancer of the fundus, in which the value of an early diagnosis is even greater than in cancer of the cervix on account of the lower operative mortality and the better prognosis as to cure.

Experimental Fat Necrosis of the Pancreas.—A number of experiments have been made by G. HESS (*Münch. med. Woch.*, April 4, 1905), to prove that apoplexy of the pancreas is really caused by entrance of fat into the excretory duct of the pancreas. If even small amounts of oil are injected into the pancreatic duct, the animals will die rapidly with symptoms of collapse and severe convulsions, and at autopsy the pancreas is completely or partially necrotic. If only a small quantity of oil be used, the animal may recover, since the necrotic tissue will be replaced by fibrous tissue. The necrosis is the direct result of the caustic action of the soap, which is formed by the action of the pancreatic juice upon the fat. Some further experiments were then made, to determine if fat can enter the intact papilla of Vater when there is stagnation in the duodenum. The duodenum was ligated 10 c.c. below the entrance of the duct, and the animal then fed with large doses of oil. At autopsy, the pancreas was found perfectly normal. In a second series of experiments the papilla was injured so as to enable the entrance of the fatty contents of the intestines. A glass tube was inserted, but the animal made a complete recovery, and no changes were found in the pancreas. It was only when both factors (compression of the duodenum and injury to the duct) acted together, that positive results were obtained. The animal showed extensive necrosis of the pancreas, and the entire peritoneum was the seat of many typical areas of fat necrosis. It is highly probable that many, if not most cases of so-called apoplexy of the pancreas in man, are brought about in this way; the stenosis

of the duodenum being caused by adhesions or the pressure of the stomach and the injury of the papilla by gall-stones or pancreatic stones. It is a significant fact that in many cases a history of cholelithiasis may be obtained. A moderate degree of indurative pancreatitis is rather common at autopsy and in many cases this sclerosing process may be the result of former attacks of apoplexy of very moderate degree.

Hodgkin's Disease with but Slight Enlargement of the Superficial Lymph Glands.—H. F. STOLL (*Med. Rec.*, May 20, 1905) says of this case that the following points seem of especial interest: (1) The development of acute symptoms associated with an eruption nearly four years after the beginning of the disease. (2) The slight involvement of the superficial glands. (3) The occurrence of periodical abdominal distention and tenderness. (4) The alternating periods of pyrexia and apyrexia. (5) The unusually severe anemia. (6) The disappearance of the glands before death. The general characteristics of the disease are discussed at length, and in regard to treatment it is stated that improvement of the nutrition by the rest cure and an abundance of fresh air is very important. Arsenic, either in Fowler's solution or as the sodium salt of cacodylic acid, should be given in relatively large doses. The glands should be exposed to the X-rays for a long period, and the earlier such treatment is begun the better will be the results. Removal of the glands is to be resorted to only when pressure symptoms are marked.

Early Diagnosis of Pulmonary Tuberculosis.—W. P. STUBBS (*Maryl. Med. Jour.*, May, 1905) states that little evidence is attainable by percussion and palpation in the early stages of tuberculosis. Auscultatory phenomena, while delicate, are audible to the careful examiner. An interrupted rythm, a weakened and rough inspiration are suggestive if found to persist over any definite area. General symptoms, even though slight, should be given careful attention. A slight hack, a constant desire to clear the throat, slight dyspnea, a localized pleuritic stitch, an indefinite neuralgic ache in the sternal or clavicular regions, accelerated pulse rate, capricious appetite, restlessness, night-sweats, disinclination to exertion, an afternoon rise of temperature, all should be regarded with suspicion. The tuberculin test should be used in all doubtful cases in the following way: A two-hour chart should be kept for three days before the injection. A one-half of a one per cent. solution of crude tuberculin is made in distilled water, and ½ to 1 c.c. (2½-5 milligrams) of tuberculin injected into a fleshy part of the body. A positive reaction is indicated by a rise of temperature, at least two degrees, over maximum temperature of the previous day, headache, backache, general malaise and nausea. The local signs in the chest are exaggerated at this time. If the test is negative the injection should be repeated after a two weeks' interval, using a larger amount of tuberculin.

SURGERY.

Surgical Treatment of Gastric Ulcer.—The following heads may be considered under this subject: First, the perforation of gastric or duodenal ulcer. Second, the occurrence of hemorrhage in gastric or duodenal ulcer. Third, chronic ulcer. Fourth, hour-glass stomach. B. G. A. MOYNIHAN (*Brit. Med. Jour.*, April 8, 1905) states that there are few catastrophes so awful in their suddenness and in their intensity as the perforation of an ulcer. Obviously if the patient's life is to be saved, it must depend entirely upon early recognition of the lesion. Perforation has usually been described as acute and chronic. The author has, however, found a number of cases which should justly be classified as subacute. In the acute perforation, the lesion occurs suddenly and completely and the intestinal or gastric contents flow directly into the peritoneal cavity. In the subacute form, the ulcer probably gives away almost as quickly as in the acute, but on account of its small size or to the relative small amount of material in the alimentary canal or possible to a plugging of the opening, the damage inflicted is less. Furthermore, typically in the subacute form, there is usually a certain amount of pain before perforation. In chronic perforation a protective peritonitis has had time to develop at the base of the ulcer. In other words, the entire lesion has been walled off. In all probability medical treatment alone cannot save any of the cases of acute perforation. For convenience of description, the author has arranged the cases of hemorrhage in four groups. In the first, it is latent or concealed, is always trivial and often inconspicuous. In the second, it is intermittent, but occurs in moderate quantity, often spontaneously and at infrequent intervals. The patient's life in this class of cases is never jeopardized from the hemorrhage, although anemia is very constant. In the third class of cases, the hemorrhage occurs generally but not always after an exacerbation of chronic symptoms. It is rapidly repeated, is always abundant. Its persistence and excess cause grave terror and will, if unchecked, be the determining cause of the patient's death. In the fourth series of cases, the hemorrhage is instant, overwhelming and lethal. In dealing with these hemorrhages, two plans may be followed. By the first the surgeon searches for the ulcers and deals with them directly. By the second he deals with them indirectly by performing gastro-enterostomy and thus giving the ulcer an opportunity to heal. First thought would suggest that the primary method should be the ideal one. It has, however, been definitely shown that in many cases it is utterly impossible to find the bleeding point. Furthermore, once found, it has been shown to be often impossible to check it. Again the bleeding is very frequently from a multiple source. Gastro-enterostomy is curative of hemorrhage for the following reason: It immediately stops the distention of the stomach. The author has not had a single case in which the arrest of the hemorrhage has not been permanent, but many prominent surgeons including Kocher, have had failures. This Moynihan ascribes in every case to the use of the Murphy button, which has fallen back into the stomach and thus continued the traumatism to the ulcer. The symptoms caused by chronic ulceration are most variable. Dyspepsia and chronic ingestion so-called are both due undoubtedly in a majority of cases, to a mechanical change in the stomach, the result of chronic ulceration. The symptoms are determined very largely by the position of the ulcer, but size and extent of the lesion are also determining factors. Should the ulcer, for example, lie in the body of the organ, it may in its contraction give rise to an hour-glass stomach. The best symptomatic results are obtained by gastro-enterostomy in those cases where the ulcer is located at or near the pylorus. Probably there is no operation in all the domain of surgery comparable to the results obtainable in these cases. As time goes on, it will undoubtedly be shown that all cases of recurring dyspepsia should be treated by surgical methods. The author has performed gastro-enterostomy in 153 cases with two deaths.

Pendulous Abdomen.—To overcome the flabby, sagging condition of the abdomen seen in women fairly well advanced in life, in women who in earlier years were corpulent with prominent abdomen, J. P. Crevelling (*Buffalo Med. Jour.*, May, 1905) suggests the removal of an oval-shaped portion of the abdominal wall from the umbilicus to the pubes. The entire thickness of the abdominal wall being removed. The author reports two cases in which all symptoms due to the condition entirely disappeared after operation and the patients remained comfortable for several years.

Traumatic Tetanus.—That traumatic tetanus is attended by a high mortality is shown by Bentz (*Buffalo Med. Jour.*, May, 1905), who states that 70 to 80 per cent. of cases die. This is probably due to the delayed effect of the toxin which is explained as follows: The toxin does not reach the spinal cord through the blood stream, but travels up the axis-cylinders of the motor cells, from their terminations. Sensory nerves do not transport toxin. Part of the toxin enters the nerves in the region of the wound, the rest is carried by the blood and lymph, to be later taken up by the motor nerves in other parts of the body. The toxin produces degenerative changes of the Nissl granules and protoplasm of the motor cells. The author considers the treatment under the following heads: (1) Thorough cleansing of all suspicious wounds, especially those contaminated by garden earth, also Fourth-of-July wounds. All wounds should be thoroughly freed of foreign matter by vigorous operative measures, and should be freely drained. The patient should receive an injection of 10 to 20 c.c. of tetanus antitoxin into the nerve trunk coming from that part. (2) Suitable legislative measures to prevent the manufacture and sale of dangerous toys. (3) Symptomatic treatment, including the use of bromides and other hypnotics and antitropin.

GENITO-URINARY AND SKIN DISEASES.

The Etiology of Urticaria.—While investigating the effect of various drugs on the skin, J. Baum (*Berl. klin. Woch.*, January 2, 1905) found that it was possible to produce typical urticaria wheals by the application of certain substances. The first drug which was followed by this effect was ethylenglykol, but a number of others were found which gave rise to similar appearances. After rubbing off the superficial epithelium with sand paper, the application of the athylenglykol produced a localized edematous swelling, similar to that of urticaria, which lasted from fifteen to thirty minutes. The writer also studied this phenomenon in the web of a frog's foot, and by the aid of a microscope was able to follow out the formation of a wheal. There was a temporary dilatation of the capillaries accompanied by a rapidly subsiding edema. There was no constriction of the veins, such as is believed by Una to be the cause of the trouble. There was no exudation of either white or red blood cells and no subsequent disturbances were noted. It is probable that the processes in the frog and the human skin are entirely analogous. It was also demonstrated that the reaction varied with the individual animals, which also seems to correspond with the fact that a particular disposition is necessary for the production of this lesion, which in the human subject may be designated as an idiosyncrasy.

Nutritive Exchanges in the Dermatoses.—That many cutaneous affections are not of local origin, but are the expression of some constitutional disturbances, is a fact well established. An experimental study of the metabolic derangements that accompany certain dermatoses was made by A. Desgrez and J. Ayrignac (*Jour. de Physiol.*, January 15, 1905). They find that in individuals affected by the most diverse forms of skin disease, only one-third have a degree of corpulence that exceeds the average. On the other hand, general adiposity is markedly increased in 53 per cent of the cases. This fact, which is observed particularly in the eczemas, furnishes a new argument in favor of the relationship pointed out long ago by M. Bouchard between obesity and the dermatoses. The catalytic excitation (the excitation to catabolism) is increased in 89 per cent. of the cases. But, in fact, the histolytic activity (destruction of proteids) is below the normal in 90 per cent. of the patients. This reduction is most marked in alopecia, and is found in the various forms of eczema. In 60 per cent. of the cases, the ratio between uric acid and urea, which normally is 2.6:100, reaches the ratio of 3, 4 and 5:100. Likewise the quantity of phosphoric acid is increased. The last two observations suggest that the excess of uric acid is due to a relatively large disintegration of the nucleo-albumins, that is, of the nuclei of the cells.

PRESCRIPTION HINTS.

For Anemic Headache.—

℞ Ferri reducti ..... gr. c
Acidi arsenosi ..... gr. iv
Phosphori ..... gr. i
Ext. nucis vomicæ ..... gr. xxv
M. Divide into one hundred pills.
Sig. One pill after each meal.

For Subacute Prostatitis.—

℞ Tinct. opii camphoratæ ..... ℥iss
Liquoris potassæ ..... ℥ii
Tinct. lupulini ..... ℥iv
Tinct. hyoscyami ..... ℥ii
Syrupi zingiberis ..... q.s. ad. ℥iii
M. Sig. Teaspoonful in half glass of water after meals and at bed time.

For Seborrhea.—

℞ Resorcin ..... gr. xl-lxxx
Glycerin ..... ♏x-xx
Alcoholis ..... ℥ss
Aquae destil. ..... q.s. ad. ℥iv
M. Sig. Apply locally every day or every two days, gradually lessening the frequency to once or twice weekly. Two or three grains of the alkaloid quinine may be added with benefit to each ounce of this solution when the tendency to alopecia is present.

For Acute Cystitis with Hemorrhage and Pain.—

℞ Morphinæ acetatis ..... gr. iv
Tinct. veratri viridis ..... ℥i
Tinct. hyoscyami ..... ℥ii
Syrupi zingiberis ..... ℥i
Aquae ..... q.s. ad. ℥iii
M. Sig. Teaspoonful in water every four hours.

For Acute Tonsillitis.—

℞ Tinct. aconiti ..... ♏xxiv
Sodii salicylatis ..... ℥i
Spiritus etheris nitrosi ..... ℥iv
Syrupi aurantii florum ..... ℥i
Aquae destillatæ ..... q.s. ad. ℥iii
M. Sig. Teaspoonful every one or two hours during the fever.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 1, 1905.

THE FOURTH OF JULY ONCE MORE.

ETERNAL vigilance is the price of liberty, according to the old saw so familiar on the Fourth of July, and it's only eternally keeping at it that will perhaps eventually secure a reasonable freedom from the fatal accidents which an ebullient patriotism now inflicts upon the youth of the land, in the celebration of the Glorious Fourth. Last year there was a special effort made all over the country to secure an amelioration of the sad conditions shown by the statistics of fatalities and injuries the previous Fourth. As the result of this campaign of education, in which the newspapers of the country almost universally joined, there was from certain standpoints a very striking improvement in the statistics, though from other points of view, they remained eminently deplorable. In 1903 the price paid in human blood for the fireworks celebration of the anniversary of independence was 466 dead and very nearly 4,000 injured. In 1904 this had fallen to 183 dead, though there were more injured than in the previous year, yet the figures approached only a little closer to the 4,000 mark.

The really noteworthy improvement in the statistics came in the matter of tetanus. Two years ago there were altogether 415 fatal cases of tetanus reported. Last year the tetanus cases amounted to only 105. This reduction of nearly 75 per cent. in the incidence of this dread disease is of itself sufficient reward for all the efforts that were made last year to secure betterment with regard to the celebration of the Fourth. It is unfortunate that it has to be added that the deaths from other causes than tetanus increased last year by more than one-half. It seems evident that as the result of the campaign of education the special class of tetanus-bearing fireworks were eschewed by many patriotic celebrants and forbidden by many parents. Much stronger explosives were employed in their stead, however, and from them came the increase in the number of deaths due to the accident itself, and an increase in the total number of accidents.

Will the improvement in the statistics of tetanus reported last year continue, and shall we have the satisfaction perhaps of witnessing a still further reduction in the number of deaths from this disease? Unless the educational effort of last year is kept up, it seems not unlikely that there will be a relapse of vigilance and as a consequence an increase in the death-rate from tetanus. Last year the public press campaign was directed mainly against the deadly blank cartridge which is so often followed by tetanus, and as a consequence, the injuries inflicted by these were less than they have been for many years. Another phase of the improvement in the mortality statistics, however, must not be passed over in silence. There is no doubt that as the result of better knowledge with regard to the possible dangers in such cases, patients themselves and parents recognized the necessity for prompt and thorough treatment of all wounds made by blank cartridges with the idea that tetanus must be prevented at all hazards. Until last year such wounds were considered as appropriately treated by ordinary home dressings, and encouraged to close as soon as possible. Even physicians had not before been aroused to the danger in this matter, and blank cartridge injuries were only in recent years thoroughly cleansed, allowed to bleed freely and in serious cases, prophylactic injections of antitetanus serum were administered with apparently good effect.

All extra effort in the care of these cases must be maintained this year and public attention should be called just as vigorously as before to the dangers that are likely to ensue. On the other hand, some of the additional dangers in-

curred last year must not be forgotten. Certain zealous parents inferred that they should apply rather strong antiseptics to blank cartridge wounds and the result was in some cases severe sloughing and in a few cases even permanent deformity. By many persons antiseptics are supposed to be quite sufficient to kill any germs that may be present, and carbolic acid is looked upon as an extremely efficient germicide. Some foolish mothers wrapped the fingers of children in gauze wet with solutions of 5 per cent. carbolic acid, and gangrene ensued. There cannot be sufficient warning of the danger of applications of carbolic acid even in solution weaker than 5 per cent. to injured cutaneous surfaces. The first effect of the remedy is to produce a numbness and insensibility to pain, as the result of which the escharotic effect of the remedy may remain entirely without symptoms, while it is working serious harm. Dressings wet with solutions of carbolic acid, however mild, must not be allowed to remain for any considerable length of time, particularly on the skin of young children.

It is sad to think that we have to face another holocaust this year and that probably at least two hundred children will fall victims to the foolish celebration of Independence Day. Besides this, about 4,000 others will be injured, nearly 1,000 of them in some serious way. In this number there will be eyes lost, legs and arms lost and many fingers mutilated with a lot of so-called slighter injuries. It is the fashion and nothing can be done. Physicians must, however, as far as is possible, exert all the weight of their authority to bring about such improvements in municipal legislation as will put an end to this yearly waste of life which is so shamefully without proper purpose and brings sadness into so many families.

THE SYNTHESIS OF ADRENALIN.

The valuable place which adrenalin holds in the armamentarium of the therapeutics of to-day has aroused the hope that some day a means of preparing this product of the mysterious chemistry of the body, synthetically in the laboratory, might be discovered. Apart from this commercial aspect, the artificial synthesis of this internal secretion cannot fail to have an important bearing on the broad subject of the physiology of the internal secretions.

H. D. Dakin (*Jour. of Physiol.*, May 9, 1905) has just reported his success in the preparation of a substance, which is not only allied to adrenalin, but also has the same chemical constitution. The details of the chemical steps necessary for this synthesis have not yet been published, nor has the identity of the natural and artificial products yet been accurately determined.

By a series of chemical processes not yet published it is possible to prepare from pyrocatechin a base having properties like those of adrenalin.

That this synthetic base is closely allied to the natural adrenalin, is indicated by the fact that the salts of the former show all the chemical reactions of the latter. But the natural substance is optically active, while the synthetic product is optically inactive. Both substances have the same physiological action, less than one millionth of a gram causing a rise in blood-pressure in the rabbit.

The author experimented with the various compounds that are intermediate steps in the preparation of the synthetic base, and found a progressive evolution of the peculiar properties of adrenalin.

The third in the series of synthesized compounds represented in the paper has a pressor effect which is insignificant when compared with that of its reduction product, the last in the series.

It has been possible to prepare a large number of allied ketone bases, and it has been found that their physiological blood-pressure raising effect bears a distinct relation to their structure. Thus the compounds having aliphatic groups (*e.g.*, methyl, ethyl, amyl and heptyl), have a greater effect than those having a mixed group (*e.g.*, benzyl), while those having a purely aromatic group (*e.g.*, phenyl, colyl, naphthyl), have, on the other hand, the effect of diminishing blood-pressure.

Pyrocatechin and its simple derivatives and homologues produce a distinct rise in blood-pressure. Moreover, substances in which the hydrogen of the phenol group is replaced are practically inactive.

The success of Dakin in discovering a product at least closely allied chemically and physiologically to adrenalin, if not identical with it, is certainly of profound interest to the pharmacologist, who may now look forward to the synthetic preparation of the other active principles of the ductless glands. To the physiologist, however, the results furnish a tempting subject for speculation. He beholds in them another extension of the conquest of modern scientific methods over the occult chemistry of the body.

It was Wöhler who first showed in 1828 that it is possible to prepare urea synthetically, and the progress in physiological chemistry has been such that an imitation of the finer chemistry of the internal secretions is no longer considered as beyond easy reach. From the practical standpoint, however, the artificial production of the internal secretions will bring these substances into the more extensive application which cheap manufacture affords.

SPIROCHAETA PALLIDA AND CYTORRHYCTES LUIS, SIEGEL.

At a recent meeting of the Berliner Medizinische Gesellschaft (May 17) Schaudinn and Hoffmann, as already outlined in the Medical News June 17, 1905, gave an account of their discovery of a special spirochaete—the *Spirochaeta pallida*, in syphilitic tissues (chancre, recent papules, inguinal glands, etc.). They also announced that Metschnikoff succeeded in demonstrating the same organism in the artificially produced syphilis of apes.

In this connection it is interesting to note that John Siegel, working in the Zoological Institute of the University of Berlin, has quite recently reported the discovery of a flagellate protozoon which he considers the specific cause of syphilis. His studies have appeared *in extenso* in the Proceedings of the Royal Prussian Academy of Sciences, of the current year.

Beyond this only a brief description of the organism—the *Cytorrhyctes luis*, from the pen of F. E. Schulze, the director of the Zoological Institute, has thus far found its way into the general literature.

It is stated that although it is possible to demonstrate numerous parasites in various stages of development in almost all the tissues of thoroughly infected apes and rabbits, the most striking pictures are obtained about three weeks after primary inoculation, with the parenchymatous juice of the kidneys. In this the organisms appear as actively motile, flagellated bodies, measuring only from 0.5 to 2.4 mikrons in diameter. They are fairly refractile, but can only be seen with the very highest apochromatic objectives, enforced by strong compensating eyepieces and the best illuminating apparatus. The larger forms appear as laterally somewhat flattened, pear-shaped bodies, provided with a single flagellum at each end, while in the smaller forms a flagellum is seen only at the tapering end. The organisms can be stained with a hematoxylin-azure mixture and can in this manner be demonstrated in sections of infected tissue. The larger forms then show two distinct round nuclei, while in the smaller bodies from 4 to 16 can be seen.

Further data are thus far not accessible, but will no doubt appear in the German weeklies in the near future, in the accounts of the proceedings of the meeting following Schaudinn and Hoffmann's paper, at which the main discussion of the subject was to take place.

ECHOES AND NEWS.

NEW YORK.

Appointment at St. Mary's Hospital.—Dr. William S. Bainbridge has been appointed consulting gynecologist at St. Mary's Hospital, Jamaica, L. I.

New Hospital for North Brother Island.—Plans have been filed with the Bronx Building Bureau for a new three-story hospital to be built on the southwest side of North Brother Island. It is to be of ornamental brick, 114 feet long and 73½ feet deep, and will cost $150,000.

Report of Health Department.—The Department of Health of the City of New York reports contagious diseases for the week ending June 24, as follows: Measles, 769 cases, 25 deaths; diphtheria and croup, 207 cases, 24 deaths; scarlet fever, 104 cases, 9 deaths; chicken pox, 115 cases; tuberculosis, 462 cases, 148 deaths; typhoid fever, 50 cases, 6 deaths, and cerebrospinal meningitis, 42 cases, 34 deaths. The death-rate for the week was 17.20 per thousand of population.

City Gets Its Sanitarium.—Dr. Thomas Darlington, president of the Board of Health of New York City, undaunted by his failure to secure a site for the establishment of a sanitarium for the care of New York City's tuberculosis patients in Sullivan County, has been quietly at work in the towns of Greenville and Mount Hope, Orange County, and has secured permission from the authorities of these towns to locate the sanitarium there. He has also secured options on several thousand acres of land, and it is now believed the sanitarium is assured. So quietly has Dr. Darlington worked that he had secured the required permission from the authorities and options on the lands before his object became generally known.

Autopsy Material in Paralysis Agitans Desired.—Dr. W. N. Berkeley, of 62 East Fifty-eighth Street, wishes to ask the readers of the Medical News who may be in a situation to help, if they can at any time put him in the way of obtaining some autopsy material from patients dying of paralysis agitans. The material of which he is in particular need can be removed without damage even as late as thirty-six or forty-eight hours after death. He will be glad to pay all the expenses that may be incurred, and will send a competent person to do the autopsy if it is impracticable for him to go himself. Full and grateful acknowledgment will be made of all help extended, if his present theory of the causation of the disease works out fully enough to warrant publication.

Staten Island Mosquitoes.—Some weeks ago Commissioner Darlington, of the Department of Health, appealed to the Board of Estimate for an appropriation of $10,000 to be used in exterminating the breeding

places on Staten Island. Comptroller Grout denied the necessity of the work, and, the majority of the Board agreeing with him, the appropriation was cut to $1,000. The New Jersey State Board of Health made remarks uncomplimentary to the spirit of the New York men, and their sarcasm prompted Dr. Darlington to send inspectors to investigate Richmond. They reported that $17,000 expended in a drainage system for the marsh lands would do away with the pest. The mayor would not believe so great a relief could be obtained at so small an expense, but professed willingness to be convinced. Dr. Doty was pressed into the service, and at noon on June 27 an inspection of the borough from the bay and ocean sides was made in one of the Quarantine boats. The mayor, Dr. Darlington, Assistant Corporation Counsel Hoyt, and Secretary O'Brien, made up the party. Borough President Cromwell met them at Stapleton.

The Need of Psychopathic Hospital.—Those who are interested in the establishing of the proposed Psychopathic Hospital in this city, for which the legislature some time ago authorized an expenditure of $300,000 contingent upon the gift of the site, may find an effective argument in the description of the recently established hospital in Munich, as given by Consul-General Mason, of Berlin, in a recent number of *Daily Consular Reports*. Mr. Mason says: "The modern psychiatrical clinic in Germany meets and fulfills two fundamental needs that exist in greater or less degree in every city or large town in the United States, namely, that the better facilities for the skilful treatment, care, and possible cure of cases of incipient and acute insanity; and, secondly, adequate provision for instruction in treatment and in the investigation of practical problems upon the solution of which must depend the arrest of increasing insanity among the people of the State. Its inestimable service to the community is that it provides for saving an indefinite but considerable percentage of the victims of incipient mental disease, and restores them to lives of usefulness instead of leaving them to degenerate into a menace to soceity and a burden to the state. It provides the most consummate examination and treatment at a stage of the disease when there is the most chance of averting or arresting an attack of real insanity. It detects and takes timely charge of the smaller but important class of patients who, without the knowledge of their friends, are on the border line of insanity, and liable at any time to become suddenly dangerous to themselves or others."

The Aftermath of Cerebrospinal Fever.—The *Herald* comments upon the meningitis situation in part as follows: "In summing up results many remarkable phases of the disease have been brought to light. The wonder is that the survivors should persist in living in spite of the number and severity of the successive complications. Children who became stricken in the beginning are still anxiously watched at death's door, with scarcely a hope that the valiant efforts of physician and nurse will be ultimately rewarded by the final recovery of the luckless victim. There have been no better examples of the severity and persistence of this disease than those that have shown themselves during the now passing epidemic. When spotted fever does not kill quickly, as it usually does in its acute and fulminating variety, it is apt to drift into a chronic form that may last for months, during which almost every vital organ may be in turn attacked by the virulent microbe. The marked fatality of the recent scourge has been in great part due to the number of brain complications that have been developed, producing profound organic lesions. In the majority of these death has been a mercy and saved the victim from the affections of blindness, deafness and mental imbecility. The most melancholy reflection in the present retrospect is that the medical profession, so skilled in other matters, is confessedly perplexed with many of the problems of this mysteriously periodical epidemic invasion. Apparently it has not yet been positively determined how the individual becomes infected, and through what particular channels the death dealing organism enters the system. Nor has any remedy been found as yet that can stay its ravages or check its course. If it is only a question of bad air and tenement life, some necessary preventive measures may be taken before the next visitation. But, theorize as we will, we are yet in sad need of facts. Perhaps the expert meningitis commission, if it can ever make a timely conclusion of its labors, may eventually settle the many disputed points at issue and give us that new hope for the future that we so sorely need."

PHILADELPHIA.

Elections.—Dr. Charles K. Mills, professor of Neurology at the University of Pennsylvania, was elected consulting neurologist at the American Oncologic Hospital, and Dr. Samuel McClary assistant pathologist.

Death from Communicable Diseases.—According to the report of the State Board of Health, 15,000 people died of communicable diseases last year. A few months ago a case of typhoid in Bucks County caused 54 of enteric fever in the Twenty-sixth and Thirty-sixth wards of Philadelphia.

To Study Leprosy in India.—Dr. Judson Daland, clinical professor of practice of medicine at the Medico-Chirurgical Hospital, has gone to India to study the effects of "Leprolin" at the lepra colony of that country. The improvement in the case now at the Municipal Hospital has induced him to go to India.

As a Prophylaxis for Tetanus.—The Pennsylvania State Board of Health has determined to supply physicians with tetanus antitoxin to be injected into individuals receiving wounds from blank cartridges on the Fourth of July. The dose shall be from 5 to 10 c.c. and shall be injected, preferably, near the seat of the wound.

Mule Develops Hydrophobia.—Dr. E. M. Gratchel, of West Chester, has in his possession a mule bitten by a rabid dog. The mule has typical symptoms of the disease which were first noticed about one week after the inoculation; the animal is isolated and is being watched, especially with reference to the progress of the malady.

Patient Puzzles Physician.—A man who said he was a locomotive engineer from St. Louis, entered the Hahnemann Hospital and stated he had been in Panama. Thinking that the patient was suffering with yellow fever he was isolated and a consultant sent for. At the consultation no exact diagnosis was made, but it was thought that the man was suffering with typhus fever.

Bequest.—Mrs. Pauline E. Henry, formerly of Philadelphia, and founder of the Germantown Hospital, died at her home in New York City May 15. She bequeathed to the institution named $10,000, the income of which shall be used to maintain two beds for incurable female patients, and $5,000 as an endowment fund. She left $2,000 for the Woman's Hospital to endow a "Scholarship for Nurses."

Reception of the Medical Club.—At this assemblage Dr. William S. Forbes, professor of anatomy at the Jefferson Medical College, congratulated the members of the club upon the fact that the hatchet has been

buried by the Alumni of the University of Pennsylvania and the Jefferson Medical Schools, and that a new era of cordial relations has been established. Addresses were made by Dr. Roland G. Curtin, president of the club, and by Dr. George Simmons, editor of the *Journal of the American Medical Association*.

Indian School will get no New Hospital.—Unless Secretary Hitchcock is able to induce the next Congress to be more liberal in its appropriation for the school at Carlisle, they will not get the new hospital which is so badly needed. At the last session, Congress appropriated $150,000 for general repairs and improvements and $10,000 for an addition to the present hospital. The Commissioner of Indian Affairs attempted to use part of the $150,000 to build an entirely new hospital instead of an addition, but Comptroller Tracewell decided against the scheme.

Aid for Consumptive Mill Workers.—Because their occupation exposes them to tuberculosis the mill workers of Kensington will receive free treatment at a dispensary to be organized and maintained by the Anti-Tuberculosis Society of Kensington. These advantages have been obtained through the efforts of Sister Marie Keck, a Lutheran deaconess, and Rev. C. S. Fry. A private dwelling bordering on the mill district will be selected for the dispensary and the same treatment will be instituted as has been adopted at White Haven. Dr. Lawrence F. Flick will be appointed advisory physician and Dr. W. G. Eisenhardt physician in charge of the work.

Dr. Dixon Names his Assistant.—Last week Dr. Dixon, Health Commissioner of the State of Pennsylvania, appointed Dr. Benjamin Lee, secretary of the recently abolished State Board of Health, Assistant Commissioner, and Dr. Frederick C. Johnson, of Bradford, McKean County, Chief of Division of Inspecting, Quarantining and Disinfecting. In a letter notifying Dr. Lee of the appointment Dr. Dixon wrote: "Your long and faithful service in the late Board of Health, which labored for many years for the good of humanity under great disadvantages, has given you especial fitness for the work of aiding me to establish and successfully build up the new Department of Health."

How Undertakers Can Aid Doctors.—In an address before the convention of the Funeral Directors' Association of Pennsylvania, Dr. A. C. Abbott spoke of "The Part Undertakers May Play in Preventing the Spread of Diseases." In the course of his talk he said that but few undertakers are open to criticism for failing to use proper precautions in regard to the spread of diseases, but the fact that there are a few makes it an important question. He maintains all instruments used for embalming should be sterilized, all clothing, furniture and carriages used at the funeral should be disinfected. Dr. Abbott mentioned the fact that he had heard of instances where the undertaker had observed all the precautions prescribed by law, but allowed the family to undo his work after he had gone.

Report of Diseases of Animals.—Governor Pennypacker met the State Live Stock Sanitary Board last week at Harrisburg and listened to the report made by Dr. Leonard Pearson, that rabies is prevalent in Western Pennsylvania and that dogs in McKean, Cameron, Warren and Venango counties are in quarantine. An outbreak of glanders in Lancaster County was reported. The investigations of vaccination of cattle against tuberculosis are progressing favorably, and it was stated that the procedure may be a success. With the view of establishing a permanent research station the board has taken steps toward buying a farm for the purpose. A resolution was adopted requesting railroad and express companies to make regular reports to the secretary of the board of the shipments of cattle from other States into Pennsylvania.

War on Tuberculosis.—In consequence of the visit paid by Dr. Paul Kennedy, of New York, representing the American Society for the Prevention of Tuberculosis to the Executive Council of the American Federation of Labor, the last-named organization has decided to extend an invitation to the Society for the Prevention of Tuberculosis to have a representative address the Pittsburg convention of the American Federation of Labor upon the subject of tuberculosis, its prevention and treatment. The representative will suggest plans by which organized labor may render effective work to arrest the disease in those suffering with tuberculosis. It was also decided to send delegates from the Federation of Labor to the congress and exposition to be held in New York next November, under the auspices of the American Society for the Prevention of Tuberculosis. So soon as the regulations complying with an act made lawful by the last legislature the Board of Health will request physicians to report all cases of tuberculosis. Dr. A. C. Abbott is of the opinion that much good will result, since the reports will indicate where the disease is most prevalent, so that overcrowding and filth can be prevented.

CHICAGO.

Appointment of Dr. Whalen.—Dr. Chas. J. Whalen has been appointed by Mayor Dunne to succeed Dr. Arthur R. Reynolds as Commissioner of Health of Chicago.

Officers of the Chicago Medical Society.—At the annual meeting of this society, held June 21, Dr. Chas. S. Bacon was elected President, succeeding Dr. John B. Murphy, and Dr. Frank X. Walls, Secretary. Reports were presented from the branch societies, the affiliated societies, from the Council, the Medicolegal Committee, the Organization Committee, Board of Trustees, and the Secretary.

Meeting of Association of Military Surgeons of the State of Illinois.—The annual meeting of this body was held at Danville, June 8, under the Presidency of Colonel Nicholas Senn. The Secretary is Lieut.-Col. Chas. Adams. A paper on "Influenza," was read by Dr. Chas. D. Center, of Quincy. Lieut.-Col. Geo. P. Marquis, of Chicago, read a paper on "Mastoid Operations." Col. Senn presented an abstract of an exhaustive article by him on "Iodine and its Use as a Bactericide;" while Capt. S. C. Stanton, of Chicago, demonstrated the method of physical examination of recruits. The next meeting of the association will be held at Moline.

Mortality Record.—While the June, 1905, health rate is not up to the record of June, 1904, according to the weekly bulletin of the Health Department of Chicago, the improvement during the week, measured by the mortality returns, will bring it higher than the average of the decade. For the elapsed seventeen days, the rate is 12.73; for the week, it is 12.01, and the average of the decade is 14.00. June, 1904, is the record month of lowest mortality, the rate being 11.02 per 1,000 of the population. Among the important causes of death showing decrease, the most notable are pneumonia, 18; consumption, 10; heart disease, 12; Bright's disease and measles, 8 each, and typhoid fever, 4. On the other hand, the acute intestinal diseases show an increase of 12; bronchitis, of 9, and diphtheria, of 4. Only two suicides were reported during the week —the fewest number in any one week for years, the aver-

age weekly number during the previous ten years being 7.5.

Permanent Home for the Chicago Medical Society.—The Committee on Permanent Home, consisting of Drs. Nicholas Senn, Wm. A. Evans, Frank S. Johnson and David J. Doherty, after several conferences with the officials of the Crerar Library and with the Newberry Library Trustees, the Committee came to the following conclusions: (1) That it is the intention of the Crerar Trustees to make their library the center of scientific activity in Chicago, and that, therefore, they will provide meeting quarters for scientific societies, and particularly will they so arrange their plans as to accommodate the Chicago Medical Society, both for its meetings and its popular lecture course. Such use of their building will be free as to rental, but incidental expenses will be borne by the society. (2) It is the intention of the Newberry Library Trustees to transfer its medical department to the Crerar Library. In this connection, Dr. Senn approves of the transfer of the Senn Medical Library to the Crerar, provided that it be kept as a separate unit and sufficient space be allowed to let it grow on the lines he has marked out. He intends to make it a great historical medical library—the progress of each department of medicine to be shown by a complete collection of books pertaining to it. (3) The preliminary plans of the Crerar Library are now being studied; the final plans will be decided on next winter; ground will be broken in the following spring, and the library building will be in use in three years.

GENERAL.

Massachusetts Medical Association. The following officers were elected at the recent meeting of the Massachusetts Medical Association: President, Dr. Arthur T. Cabot, of Boston; Vice-President, Dr. Frederick H. Thompson, of Fitchburg; Treasurer, Dr. Edward M. Buckingham, of Boston; Corresponding Secretary, Dr. Francis W. Goss, of Roxbury; Recording Secretary, Dr. Edward H. Brigham, of Brookline.

Dr. Kelly in London.—Dr. Howard Kelly, Professor of Gynecological Surgery in the Johns Hopkins University at Baltimore, was entertained at dinner by Dr. Macnaughton-Jones at the Cafe Monaco, London, on June 8. Immediately after dinner those present went to 20 Hanover Square, where Dr. Howard Kelly delivered to the British Gynecological Society the address on "Some Surgical Notes on Tuberculosis of the Kidney," which is published in the *British Medical Journal* for June 17, 1905.

Alaskan Medical Association.—At Nome, Alaska, the medical men of the far Northland recently met and organized the Northwestern Alaska Medical Association. There are ten or more charter members and the officers elected for the current year are A. L. Derbyshire, President; H. S. Moore, Vice-President, and W. D'Arcy Chace, Secretary and Treasurer. Several profitable and pleasant meetings have already been held. This is probably the first medical organization in Alaska and the most northerly one under the stars and stripes.

To Stop Cut Prices on Patent Medicines.—Strenuous measures are being adopted by practically all the manufacturers of the best known preparations, who are compelling all retail druggists to sign ironclad contracts not to sell the goods in question at less than a rate fixed much higher than those which have been prevailing. For some time it has been understood that goods would not be sold to dealers known to cut prices, but this was a rule easily evaded. Now, however, it is announced that the contracts will be rigidly enforced, and a system of numbered packages is contemplated to assists the manufacturer in keeping track of the dealers and their prices.

Esquimaux Obstetrics.—Last year the wife of a Bostonian at Cape Prince of Wales, was pregnant with her third child. Previous labors had been difficult. When she was in labor no physician was to be found within 150 miles. Her husband called in two Esquimaux women and explained the case. They at once made a belt of stout muslin about ten inches wide and took a turn around the patient's body at upper limit of tumor. Then a long pull, a strong pull and a pull all together and the delivery was accomplished with neatness and despatch. Everything was lovely. This is absolutely authentic asserts Dr. W. D'Arcy Chace, of Nome, Alaska.

Medical Society of the Missouri Valley.—The annual meeting of this organization will occur on Thursday and Friday, August 24 and 25, in the city of Council Bluffs, under the presidency of Dr. S. Grover Burnett, of Kansas City. The local arrangements are in the hands of Dr. V. L. Treynor, and an able corps of assistants, and this means a good time. Two symposiums, one on "Pulmonary Tuberculosis," and the other on "Diabetes," will be presented. Those who wish to contribute papers on these or any other subject, should communicate with the secretary at once, as the program will be limited, and papers will be placed in the order in which the titles are received.

Charities and Corrections.—The National Conference of Charities and Correction meeting in Portland, Oregon, on July 15, announces the following program for the evening session of July 20: Committee on Care of the Sick: "Report of Committee," by Nathan Bijur, President New York State Conference of Charities of 1905. A general report covering three phases of the dealing with the sick as follows: "Prevention of Diseases by Improved Housing, Sanitary and Economic Conditions," by Dr. Norman Bridge, of California: "The Actual Care of the Sick in Hospitals, and Care of the Sick in their Homes," by Dr. Walter Lindsley, of Los Angeles; "Convalescents: Their Care from the Medical Standpoint and Light Employment for Them," by Dr. Lee K. Frankel, Superintendent United Hebrew Charities of New York. A discussion will follow.

Bubonic Plague on Isthmus.—Reports from Panama assert that a fatal case of bubonic plague occurred at La Boca on June 23. The constant arrival of steamers from infected South American ports, which are recived at La Boca without any extra precautions, must be a source of contagion. The dead man had been working on board the British steamer Chili, which the authorities of Guayaquil would not allow to enter that port. The companions of the dead laborer have been isolated. Rats taken from the steamer Chili are now being examined at Ancon. The Board of Health of Guayaquil, Ecuador, on June 12, refused to admit the British steamer Chili, which had arrived there the day previous from Iquique, Chili, and she left later the same day for Panama. While the Chili was on her way to Guayaquil three persons died on board, and it was believed that bubonic plague was the cause of their death. La Boca is a small place about three miles from Panama, with which it communicates by a plank road.

Woman's National Sabbath Alliance Asks Cooperation.—The attention of the Woman's National Sabbath Alliance having been called to the harmful effect of overtaxing brain and nerves, resulting from incessant excitement and toil, appeals to the medical faculty for a leaflet of not more than 2,500 words, demonstrating the urgent need of a weekly mental and physical rest-day

as appointed of God, for the moral and religious welfare of man, and offers a prize of $25 for the best essay on this subject. The experience of a Christian physician is preferred. Manuscripts with the name and address of the writers in a sealed envelope, will be received until the first of November next, at the headquarters of The Alliance, Room 709, 156 Fifth Avenue, New York City. The accepted manuscript shall become the property of the Alliance, and the others will be returned when called for or accompanied by the full amount of postage needed.

A Modern Hospital for the Insane.—In a recent issue of *Daily Consular Reports,* United States Consul-General of Berlin describes the new psychiatrical clinic at Munich, "which, in all that relates to perfection of equipment and arrangement, as well as to the scientific enlightenment of methods employed, stands undoubtedly at the head of all institutions of its class in this or any other country. The edifice includes the central or administration building, with two wings, which form the front and sides of an open court or garden. In the central structure are located laboratories for pathological, chemical, and psychological studies, a fine medical library, rooms for the reception and examination of patients, and the private rooms of the director. The apparatus and facilities for every form of research connected with any question relating to preventing, detecting, and curing insanity are as elaborate and perfect as experience and up-to-date science can suggest. It has accommodations for 110 bed patients of both sexes, besides a large dispensary on the ground floor for the treatment for voluntary patients who come in at stated periods, but live otherwise at home. Although opened only a few months ago, the clinic will have treated not less than 2,000 patients before the close of its first year. For this hospital, with only 110 beds, the city of Munich, a city of 280,000 inhabitants, was willing to spend $500,000."

Hospital Interne (Male). Examination for Panama Canal.—The United States Civil Service Commission announces an examination on July 12-13, 1905, at the principal cities of each State, to secure eligibles from which to make certification to fill vacancies in the position of hospital interne under the Isthmian Canal Commission on the Isthmus of Panama. Each applicant for the Isthmian Canal Service will be required to submit to the examiner, on the day he is examined, a photograph of himself, taken within three years, which will be filed with his examination papers as a means of identification in case he receives appointment. An unmounted photograph is preferred. The date, place, and kind of examination, the examination number, the competitor's name, and the year in which the photograph was taken should be indicated on the photograph. Age limit, twenty to thirty years on the date of the examination; salary, $50 per month, with board and quarters, provided that if appointees are retained in the position of interne after one year they will be paid $125 per month. Only graduates of reputable medical schools having a three years' course will be admitted to this examination. The county officer's certificate in the application form need not be executed. Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the board of examiners. The medical certificate in Form 1312 must be filled in by a reputable practising physician. No application will be accepted unless properly executed and filed with the Commission at Washington. In applying for this examination the exact title as given at the head of this announcement should be used in the application

Civic Duties of Physicians.—At a recent meeting of the Massachusetts Medical Association Dr. Louis D Brandeis delivered a lecture on the political duties of the physician, taking as his text the failure of the city government to build the hospital for consumptives. This failure he attributes to the fact that "physicians are of no political significance," "Despite your numbers and your education, your college and your university degrees, you count as nothing politically when compared with the great leisure class employed by the street department, or, indeed, the employees of less favored departments. For you may well bear in mind that of all the $3,426,600 appropriated for various purposes in the loan bill of July 3, 1901, this $150,000 for your consumptives' hospital is the only amount which has not been expended; indeed, nearly two years ago it figured as the only authorized loan under that bill which had not been paid. That master sanitarian, Gen. George F. Waring, discovered the method of cleaning New York's streets. It was 'to put a man instead of a voter at one end of a broom.' I think the converse of that is true with respect to your movements in aid of public health. To accomplish your ends we must have a voter as well as a physician behind your effort—a vote to enforce the effort of each one of you to advance your cause. As I stated at the outset, intelligently working citizenship is essential to the success of your beneficent plans, and this intelligent working citizenship necessarily involves not merely your participation as voters in city affairs, but your organized participation. Your citizenship can be an intelligent, a working citizenship only through organization. You must connect yourself with other forces that are active for good government, and fortunately the existence of the Good Government Association affords you an easy means toward the organization of your forces. The Bar Association, the Merchants Association, the Fruit and Produce Association, and others have all joined forces in an effort to secure a better city government. Must not you do likewise in order to accomplish your ends?"

Mental Phenomena Connected with Anesthesia.—The following circular letter issued from the department of psychology, Wisconsin University: While in the deeper stages of anesthesia mental processes are usually so entirely submerged as to fall beyond the possibility of record, in the lighter stages and in the period of approach to, and most favorable of all, in the period of recovery from more complete anesthesia, the power of response to outward stimuli is sufficient to afford ample opportunity for a series of observations which furnish the motive to the present inquiry. The cooperation of surgeons and anesthetizers is invited to secure data that bear upon any of the questions summarized below, or upon the general problem thus suggested. Special attention is directed to the importance of tracing relations between the phenomena recorded during anesthesia and the normal, waking, mental traits of the subject. Indeed the former can in many cases be interpreted only in the light of the latter; and observations become of value in proportion as the subject is able to account for the mental experiences of the unusual state of references to the normal source and trend of his mental processes. To determine these, skilful questioning controlled, where possible, by ingenious tests, will be the most effective instrument of inquiry.

(1) *Analogies Between the Lighter States of Anesthesia and Hypnosis.*—Of these the chief trait is *increased suggestibility:* Will the patient carry out automatically with enfeebled consciousness suggestions given by the operator to do thus and so, to feel or neglect certain sensations, to follow a train of thought, to carry

out a code of signals between subject and operator? Is obedience to such suggestions apparent by facial expressions, involuntary cries, nods, etc., after more controlled forms of reaction have disappeared? Is there evidence that patients respond to similar suggestions not directly addressed to them? Do they react to the conversation of the attendants, to a vague knowledge of their surroundings, to interpretations, correct or incorrect, of what is actually going on? Are there any of these responses that reflect the normal habits, idiosyncrasies, etc., of the waking condition? Do they belong to the experiences immediately preceding or to a more remote past? Next in importance are the automatic activities. Illustrations are desired of automatic talking, mechanical acts, and simple tricks of manner, of the type so common in sleeping persons who walk and talk in their sleep, answer questions without awakening, make movements as of knitting, counting money, etc., or other betrayal of their subconscious thought. In very favorable instances, it may be possible to place a pencil in the patient's hand and secure by questioning a subconscious answer or scribble or drawing that throws interesting light upon what is going on in the mind, even when there is but partial consciousness of surroundings or direction of mental processes. Such observations have especial value and should be accompanied by the actual records.

(2) *Analogies Between the Lighter States of Anesthesia and Dream Life.*—If the patient be questioned as to what occupied his mind up to the moment of losing consciousness and again during the regaining of full consciousness, there will inevitably result a valuable collection of data regarding the waning and waxing states of consciousness. Many of these phenomena will be dream-like, and should like dreams be recorded with ample detail to make them intelligible. The nature of the impressions, whether visual or auditory, acted or felt, and most of all the connections between the dreams and the recent or remote experiences of waking are important items. Just as ordinary dreams become interesting when they are connected with normal experiences, so in the dreams of anesthesia the patient alone can give adequate personal detail to give significance to the narrative.

(3) *Other Points of Interest.*—The specific points enumerated are intended to make the matter definite rather than to limit the scope of the inquiry. Evidence is desired that bears in any degree of pertinence upon the general problem thus suggested. As additional points of interest may be mentioned the following: In cases of repeated anesthesia after rather brief intervals, it is possible to elicit evidence that in the approaching or receding consciousness, details are remembered (or recallable by suggestion) which though beyond the control of the waking consciousness, are thus shown to connect one state of abnormal consciousness with another similarly caused. The analogous fact is that in hypnosis the subject will tell in a second hypnotization what happened while he was formerly hypnotized, but cannot recall in the waking interval; or again, in changes of personality the relapse into the altered personality will bring with it the control of memories of the last states of abnormal personality, which were not recallable in the normal state. Dreams and the actions of drugs show similar phenomena. Where records of this kind are available through anesthesia, they should be recorded in detail, and a conclusive set of questionings and tests be made to elicit how far the two states are connected. A further point of interest is the correlation of different types of mental states with different degrees of anesthesia. For this purpose it is desirable that some physiological sign of the degree of anesthesia be recorded as evidence in general of the depth of anesthesia during which the mental phenomena were observed. The variations of susceptibility to an anesthetic are such as to make it important to estimate the susceptibility in each case, as well as to give such general data as the age, sex, occupation, condition in life, physical state, temperament, purpose for which the anesthetic was administered, length of period under its influence, degree of nervous shock accompanying the same, and so on. The general use to which the data will be placed will be that of formulating a consitent account and interpretation of the range of subconscious mental states, including simple states of distraction, absent-mindedness, reverie, trance, hypnosis, dreams, the actions of drugs, alterations of personality, lapses of memory, states of confusion, and the reactions to anesthetics. It is hoped that a sufficient series of data will be elicited by the present inquiry to throw important light upon processes as yet imperfectly understood, and the analogies of which to such artificially induced states as those accompanying anesthesia are of especial importance. The psychologist has naturally but little opportunity to observe these phenomena and must thus appeal to those who are professionally engaged in their production, to step aside from their main interests to supply in a spirit of cooperation the data so valuable to students of a different and yet not unrelated science. Full credit will be given to all contributions, and no direct or personal use will be made thereof in print without distinct permission. Those to whom this circular letter is addressed are hereby invited to send records of such observations and to further the purposes of this inquiry in such ways as may lie in their power. The undersigned will appreciate, both personally and professionally, favorable action upon this request. Joseph Jastrow, Madison, Wis.

OBITUARY.

Dr. Walker Bryan, of 105 Madison Avenue, New York, was found dead in a chair in his office early on June 26. Dr. Bryan's body was removed to the home of his parents at 372 Clermont Avenue, Brooklyn. He was thirty-eight years old and a graduate of the College of the City of New York and the College of Physicians and Surgeons. He had been practising for fifteen years. He was a member of the faculty of the Brooklyn College of Pharmacy and leaves a widow.

Dr. John H. Hinton.—At a stated meeting of The Medical Association of the Greater City of New York, held June 12, 1905, the following report was presented and adopted:

Dr. John H. Hinton, one of the founders of this association, was born in the City of New York in 1827, nearly four score years ago. He was the son of John and Helen Frazer Hinton, also of New York City. Dr. Hinton was one of the rare examples of a typical New Yorker. Since early youth he had watched with civic pride, the marvelous development and wonderful progress of the old town to the Greater City of New York. Places that once resounded with the echo of his gun while hunting for game are now compact city blocks. Places where he gathered specimens for his cabinet of minerals are now covered with palatial dwellings. He received his medical education at the College of Physicians and Surgeons of this city and was graduated in 1852. He then spent two years in Germany, continuing his studies in special branches. After his return he was married to the daughter of Henry Elswood, a merchant of New York. She and three chil-

dren survive him. For many years he was associated with Dr. Alfred C. Post, whom a few of us can remember as a genial and lovable man. One of Dr. Hinton's children bears the doubly honored name of Alfred Post Hinton. At the outbreak of the Civil War Dr. Hinton entered the United States Army as surgeon. At the close of the war he was appointed visiting surgeon to the Presbyterian Hospital. Dr. Hinton, though deeply interested in everything that pertained to his profession, was fortunately not dependent upon it for his support, and found time to apply himself to those pursuits which attract a man of culture and means. He was an enthusiastic and discriminating lover of rare books, and his collection, the product of years of search, is, in its various branches, one of the most valuable in the city. He was also fond of the drama in its higher and better forms, and for many years was the friend of Joseph Jefferson. Two of the chief traits in Dr. Hinton's character were his outspoken candor and his sterling integrity. He was for many years treasurer of the New York Pathological Society, treasurer of the Society of Widows and Orphans of Medical Men and treasurer of the American Folk Lore Association. As a citizen interested in the welfare of the State and Nation, he was a member of the Union League Club; as a patron of the drama, a member of the Grolier and Players' clubs. In art and natural science he filled a place in the Metropolitan Museum of Art, the American Museum of Natural History, the American Geographical Society, and the New York Botanical and Zoological societies. A broad-minded man of diversified tastes, a sincere man, a man of unswerving integrity, loved and respected, his life filled with years and honor, after a lingering illness of some two months he passed over to the great majority to receive the reward of faithful service, on April 26, 1905. Your Committee, in presenting this record, offer the following resolutions:

RESOLVED, That by the death of Dr. John H. Hinton this association has lost a distinguished and honored member.

Resolved, That we extend to the bereaved family our profound sympathy for them, in this, the time of their sorrow. (Signed) R. E. Van Giesen, *Chairman;* P. Brynberg Porter, J. Blake White, *Committee.*

CORRESPONDENCE.

LATUREN VS. BOLTON DRUG COMPANY.

To the Editor of the MEDICAL NEWS:

Perhaps the most remarkable legal opinion on a medical subject which has ever emanated from the Supreme Court of the State of New York is the following, which was handed down on May 15, 1905, by Mr. Justice Gaynor, in the case of Laturen *vs.* Bolton Drug Company:

"SUPREME COURT, STATE OF NEW YORK,
(Second Department).

Emma F. Laturen
vs.
Bolton Drug Company.

Action for damages for alleged negligence in filling a physician's prescription, by which the plaintiff claims to have been poisoned with morphine.

Motion for a new trial on the minutes, the Court having dismissed the action on the evidence produced by the plaintiff.

Edmund F. Driggs for the plaintiff.
Charles C. Nadal for the defendant.

Gaynor, J.: The charge in the complaint against the defendant is negligence by its pharmacist in filling a prescription of Dr. Cruikshank for the plaintiff, by which she was poisoned by an overdose of morphine or opium, as is claimed.

The prescription was in the following words, viz.:

"Elixir Pinus Comp. cum Heroin, ounces 4—Merrill's. One teaspoonful in water every four hours."

The pharmacist saw that it only called for a patent medicine put up and sold in bottles by Merrill (at Cincinnati). It did not call for an original bottle of the medicine, but for a smaller quantity in a four-ounce vial. There was a bottle in stock, the printed label thereon bearing the name "Elixir Pinus Compositus," which the prescription called for, and that being the name under which the medicine was advertised and sold. But the pharmacist saw that the doctor's prescription had, after the name of the said elixir (as we have seen) the additional two words "cum Heroin," which is Latin for "with" Heroin.

These two words were not on the label of the bottle. The pharmacist therefore looked into the pamphlet advertisement of Merrill's patent medicines, which he had in the store, and found that Merrill also put up the said "Elixir Pinus Compositus" in the same bottles with the same name on the label, but with the additional two words under it on the label, "with Heroin," not "cum Heroin."

The formula given by the pamphlet also showed that the amount or proportion of Heroin was 1-24 of a grain to the dram, or teaspoonful dose. The pharmacist therefore, in order to fill the requirement of the words "cum Heroin," in the doctor's prescription, added the said 1-24 of a grain of Heroin to the dose, and thereby literally filled the prescription which, as we have seen, called for "Elixir Pinus Comp.," with the added two words "cum Heroin" (with Heroin).

There was plainly no negligence in this. The prescription was none too careful; it did not even correctly follow the words of the label of the patent medicine bottle it was filled from; but it was intelligently read and filled.

It is claimed, however, that there was a negligent oversight by the pharmacist, in that he let in one ingredient too many.

The pharmacist properly added 1-24 of a grain of Heroin for each dose, but it is claimed that he negligently left in 1-16 of a grain of morphine acetate for each dose.

And that came about as follows: By the formula printed on the bottle label the said "Elixir Pinus Compositus" is shown to consist of nine separate drugs in certain proportions, the seventh being the said "Morphine Acetate, 1-16 gr."

By the formula printed on the label of the bottle of the other mixture, *i. e.*, of the said "Elixir Pinus Compositus, with Heroin," it is shown to consist also of nine separate drugs in certain proportions. They are the very same as those on the label of the bottle of the "Elixir Pinus Compositus," except that the seventh, morphine acetate (1-16 gr.) is omitted, and Heroin (1-24 gr.) is substituted in its place.

The pharmacist, however, added the 1-24 grain of Heroin the dose to the bottled "Elixir Pinus Compositus," which contained the 1-16 grain of morphine acetate to the dose, as we have seen; wheras, if the prescription had been filled from a bottle labeled "Elixir Pinus Compositus, with Heroin," the 1-16 grain of morphine acetate would not have been in it, as it is omitted from that bottle, as we have seen.

The question, therefore, arose whether, if it be conceded that this was a negligent oversight by the pharmacist, the plaintiff could have been poisoned by it.

Heroin is a preparation of morphine, as is also morphine acetate; so that the two together in the prescription

made more morphine to the dose than if the 1-24 of a grain of Heroin only had been in it.

But the uncontradicted evidence in the case is that both combined would make only 1-10 of a grain of morphine to the dose. And there was no evidence whatever in the case that 1-10 of a grain of morphine in a dose, taken every four hours, could cause morphine poisoning. On the contrary, the uncontradicted evidence is that it could not do so, but that 1-5 of a grain increased to ¼ of a grain every hour would be usual and entirely safe; whereas the plaintiff's dose was only 1-10 of a grain every four hours, and she took only four doses. When we consider that morphine is not a cumulative poison, but that no effects of a dose of 1-10 of a grain, or even of a much larger dose, would remain in four hours after it was taken, we perceive the entire lack of foundation to the claim put forward for this plaintiff that she was poisoned by morphine.

On this state of the evidence it did not seem to me that there was any evidence on which the jury could be permitted to find that the plaintiff was poisoned by an overdose of morphine, and I therefore dismissed the case. It was not for the jury to guess; the fact had to be proved. I would now grant a new trial and send the case to a jury did I not remain of the same opinion. Moreover, I believe that a Court may take judicial notice of the scientific fact that 1-10 of a grain of morphine taken every four hours could not have poisoned the plaintiff.

It is very evident that the names on the two bottles are, taken together, very misleading. The name "Elixir Pinus Compositus with Heroin" is obviously wrong, for the contents of the bottle are in fact "Elixir Pinus Compositus," not merely "with" Heroin, but also "without" morphine acetate. For this reason the doctor's prescription was negligent. It should have unmistakably distinguished between the two bottles, since the names on their labels did not.

My attention is called to the fact that the doctor has published in a medical journal, and otherwise, the false and invented statement that it was decided in this case that a pharmacist may change a doctor's prescription, or substitute some other medicine than that it calls for, without liability. I regret to feel obliged to say that he is so well known in our courts, where he has been for many years connected with litigations of an unsavory character, to say the least, that no notice needs to be taken of his false statement so far as the legal profession is concerned, and I understand that to be so of the medical profession also. But lest any drug clerk may be misled by such false statement to the danger of others, it seems proper that I say that not only was no such thing said or decided, but it was not presented or even mooted. Where would counsel be found to present and argue such an absurd proposition?

The motion is denied."

This opinion is remarkable in all respects, but it is probably unprecedented in the history of medical jurisprudence, because of the glib and flippant manner with which the learned Trial Justice, in dealing with the important subject of the administration to human beings of so poisonous a drug as morphine, completely ignores therapeutic and toxicological authority.

When this opinion is examined in the light of medical science, it will be found so thoroughly deficient in knowledge of the medical subjects under consideration as to cause every thoughtful physician to shake his head in despair. Were it not for the fact that the opinion in question is handed down from a Court of the highest original jurisdiction, and also for the fact that the subjects with which it deals are those which closely concern the health and even the lives of human beings, it would be unworthy the serious consideration of any member of our profession.

Under the present circumstances, however, the opinion, it seems to me, should not escape the thoughtful attention of the entire community.

The idea of Divine right of personal government in our country perished in giving birth to the "Declaration of Independence;" therefore, it is no longer claimed that our courts should be infallible; on the contrary, it should be understood that their decisions, in the very nature of things, can, at best, represent nothing more than the accumulated expressions of long periods of human thought and action.

In full recognition of this fact, the thinking, law-abiding citizen, realizes that judicial opinion is necessarily and unavoidably, not infrequently, capable of a variety of constructions. Nevertheless, the great tendency of our present civilization is to bow down in reverential silence to the official acts of our judges, and, in the vast majority of instances, justly so, because these official acts represent the highest integrity of purpose.

I think I may venture the assertion, without fear of contradiction, that the profession of medicine is particularly conservative in its handling of public affairs—perhaps too frequently refraining from criticism of judicial expression concerning matters which are considered strictly within its sphere. Be this as it may, our profession should not lose sight of the fact that under our system of government the judiciary is the servant of the people, and not the people the servants of the judiciary. Judicial function is the proper construction of legal tradition, together with the equitable construction of those statutes which are made by the people in lawful assembly. These statutes should in themselves be the great voice of the commonwealth, and must be construed in the interests of law, order and public policy. It is one of the duties of the medical profession to safeguard the public health. It is its business to see to it that proper statutes are enacted, where medical matters are concerned, and it is also its function, when necessary, to enlighten the Courts with its special knowledge, in order that a just construction of these statutes may obtain. Its conservatism in this direction may be carried too far. Indeed, it has already been overreached. There is room for far greater concerted medical activity in matters of real practical importance to the community. The profession of medicine should not be blinded, in its pursuit of microscopic scientific investigation, to the necessity for careful consideration of some of the nearer things of everyday life.

When the medical profession of the great State of New York, the fountain-head of medical science in this country, is suddenly confronted with an opinion which is handed down from the Supreme Court, violating an elementary legal principle, and thereby shattering to its very foundation the usefulness of the physician's prescription as an order to the druggist, it is time that some concerted medical action should be taken in the premises.

When it is realized that this opinion distinctly holds

First: That there is plainly no negligence on the part of a druggist who tampers with the physician's prescription, even when this prescription calls for the dispensing of such dangerous and potent drugs as opium.

Second: That the substitution in the dispensing of a physician's prescription of one preparation for another is justifiable.

Third: That "morphine is not a cumulative poison," and that certain well-known poisonous doses of this drug *could not* be poisonous in their effects, thus flying directly in the face of accumulated scientific knowledge,

Fourth: That "no effects of one-tenth of a grain of morphine, or even a much larger dose, would remain in four hours after it was taken,"

Fifth: That a strictly ethical pharmaceutical preparation, the formula of which is published on each label, is a "patent" medicine,

Sixth: That a physician's prescription was negligently written, because in writing said prescription the physician did not name the ingredients he wanted *left out of the prescription,* as well as those he wanted the druggist to put in it,

Seventh: That the prescription was not carefully written, because the writer of it used the Latin word "cum" Heroin, instead of the English word "with" Heroin, so that in this manner, says the learned Court, "the prescription did not even follow the words of the 'patent medicine' it was to be filled from;"

And when we still further realize,

First: That at the trial of the cause the testimony of the druggist (who was actually guilty of substitution in the preparation of the prescription in question, and who also dispensed in said prescription a preparation containing 1-16 of a grain of acetate of morphine to each dose, whereas no acetate of morphine whatever was prescribed) was guiding to the learned Court as to a proper and safe quantity of morphine to be administered to the plaintiff,

Second: That this druggist further testified at the trial of the case, and the learned Court admitted his testimony in evidence and was guided by it in dismissing the complaint, that 1-16 of a grain of the acetate of morphine and 1-24 of a grain of Heroin added together equaled 1-10 of a grain of morphine, and also that this was a perfectly safe dose of morphine to give to the plaintiff, whom he had never seen, and concernig whose age, physical condition, or susceptibilities, he knew absolutely nothing.

Third: That this "chemist expert," whose testimony was guiding to the Court as to the proper and safe dose of morphine which should be administered to the plaintiff, swore that he was not a physician; that he had never received a medical education; that he did not know what was the matter with the plaintiff at the time he made the substitution in the prescription, and also that he had received his knowledge concerning the effects of morphine on the human system from the "National Dispensatory,"

Fourth: That this druggist further testified that ¼ of a grain of morphine given every hour "might put a patient under the influence of morphine," and also that ¼ of a grain of morphine administered every hour to a patient weakened in consequence of uterine hemorrhages, would have no more effect than if the person to whom these doses were administered was in perfect health, and furthermore, that ¼ grain doses of morphine would have "the same effect on every adult,"

Fifth: When we consider that the doses of morphine which this "chemist expert" informed the learned Court "might upset a patient" namely, ¼ of a grain every hour, would in all reasonable certainty, had such doses been administered to her, have killed the plaintiff in this action, and also that the administration of such doses, and even much smaller doses, has, over and over again, been followed by serious, and sometimes fatal results, particularly in persons where idiosyncratic tendencies have existed, but more especially in the cases of children and the aged and enfeebled with disease,

Sixth: That the testimony of the family physician, who swore positively that he found the plaintiff suffering from opium poisoning, describing to the Court her symptoms with considerable detail, was completely ignored by the learned Trial Justice, although this physician testified that he had been in the habit of regularly professionally attending the plaintiff for over twenty years, and by reason of such attendance he was in a position to know her peculiarities of constitution, together with her drug idiosyncrasies.

Seventh: And when to all this is added the fact that the learned Trial Justice, in rendering his opinion, resorted to judicial blackguardism for the sole purpose of supporting his foolish contention, it seems to me that it is the duty of the medical profession to speak on the subject in no uncertain voice. The play to the gallery should cease, and the competent critic should pierce the veneer of judicial farce with the keen searchlight of scientific truth. When well-settled and lawful medical principles, which have for their object the sole purpose of the protection of human life, become imperiled by farcical judicial opinion, "opera-bouffe" must give way to tragedy, and the play should take on a serious aspect.

I regret that a lack of time at this moment will not permit of a more complete and detailed exposure of the medical absurdities which are to be found in the text of the opinion as handed down by the learned Court. I will, however, make this detailed examination the subject of my next communication. Meanwhile, if I may be permitted a word concerning that part of the learned Court's phraseology which is devoted to myself, I desire to say that my personality, it seems to me, is entirely irrelevant to the issue.

Is it possible that the unsavory odor of defeat which was wafted down the river from Albany twenty years ago, in the case of "Cruikshank *vs.* Gordon," is still fresh in the memory of the then defendant's attorney?

This case (118 N. Y., 178) also interested the medical profession because of the principles involved, and there was at that time a very decided difference of opinion on the involved propositions of law between the learned Trial Justice, who was then at the bar, and the Court of Appeals.

"Unsavory" in the delicate nostrils of the learned Trial Justice as I may still be, the question here at issue remains the same. It cannot be deviated from in the slightest degree. No indulgence on the part of the learned Trial Justice in venom and personal abuse can by any possibility alter it.

Has the druggist the right to tamper with the physician's prescription, and has Mr. Justice Gaynor, in the case of "Laturen *vs.* The Bolton Drug Company" so held?

This question, together with the question of my professional reputation, I am perfectly willing should be left with the members of my profession with whom I have labored continuously and, I venture to hope, honorably, here in Brooklyn for twenty-five years.

With regard to the piteous and undignified spectacle which is presented to the community by the learned Court in its judicial use of irrelevant and abusive language in referring to a citizen and taxpayer, I have no opinion to offer, preferring to leave the question where it properly belongs, in the hands of Mr. Justice Gaynor's associates of the bench and bar. It may not, however, be considered unreasonable to add that such evidences of lack of judicial temperament can have no other effect on the mind of the average citizen than to cause him to give serious reflection to the question as to whether the source from which such undignified, irrelevant and venomous language emanates, is the judicial power to which grave matters appertaining to the public welfare should be submitted for impartial and rational adjudication. Very truly yours,

WILLIAM J. CRUIKSHANK.

June 6, 1905.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held February 16, 1905.

The President, Charles A. Dana, M.D., in the Chair.

Contributions to the Pathology of Sciatica.—Dr. J. Ramsay Hunt reviewed the literature as to the pathological findings in cases of sciatica, and showed that there was a general consensus of observations with regard to a swelling of the nerves. Some English observers thought they observed uric acid in the neurilemma. It seems very probable, however, that these deposits were secondary. In most reported cases, the nerve was found redder and more voluminous, being usually less dense than normal. In one case the sheath was found to be loosened, with some dilated veins around the nerve, but no sclerosis of the nervous tissue. In one case it was thought that more fat was present in the nerve than normal. Out of the 11 cases reported, three were negative pathologically and the eight that were positive, showed an increase in size, though without much nerve change.

Typical Attack.—Dr. Hunt's patient suffered from left sciatica which disappeared after six weeks of treatment. It recurred again the next year. There were tender points, especially at the exit of the nerve, and there was some numbness on the outside of the limb, with coarse fibrillary twitchings. The patient died from intercurrent pneumonia and at the autopsy the left sciatic nerve was found thicker and more voluminous. This thickness was due to the deposit within the sheath of a firm jelly-like substance. No redness and no edema were noted. In this firm translucent substance no uric acid could be found. There was no evidence of round cell infiltration or of acute inflammation. There were no histological changes in the nerve itself and no fibrin and no degeneration. These autopsy findings seem to be somewhat in accord with those described as found in previous cases. Just what their significance is is not clear.

Possibility of Syphilis.—Dr. B. Sachs said that Dr. Hunt's case would seem to be entirely exceptional and not at all likely to prove a typical example of the ordinary pathological condition underlying sciatica. There is a possibility that the pain in this case may have been due to syphilis. Gelatinous deposits from syphilis have been found along the spinal cord, and indeed there is no other pathological condition in which jelly-like changes are known to occur. A specific perineuritis simulating ordinary sciatica is not as unusual as has been thought.

Sciatica and Uric Acid.—Dr. James J. Walsh said that it seems unfortunate that whenever there is discussion of a neuritis of any form, it is always considered necessary to haul in the mention of uric acid. The roll of uric acid has been entirely too much exaggerated and it seems unlikely that it ever causes any of the forms of neuritis which are spoken of as rheumatic. Indeed most of the neuritises are due to overwork of a particular group of muscles with consequent lowered resistive vitality of the nerves supplying them, so that they become more liable to attack from infectious agents. It is in an overworked nerve that such toxic substances as lead and alcohol are likely to produce their manifestations and still further add to the likelihood of an inflammatory neuritis resulting. Men who work outside with a pick and shovel, bending frequently at the hips, are especially likely to have their sciatic nerve affected if at the same time they drink freely of alcohol. In such cases there is no need to think of uric acid in the case and no justification in medical literature for the introduction of the term, which serves only to perpetuate an old-time fallacy, yet unfortunately is supposed to furnish indications for treatment.

Less Sciatica.—Dr. Robert Morris said that as the result of more intrapelvic work in both males and females in the removal of prostates and tumors of the pelvis, sciatic nerves are much less predisposed than formerly to become affected by inflammatory reactions of various kinds. As a consequence, fewer cases of sciatica now come to the surgeon for nerve stretching and other modes of relief. When nerve stretching was more common, it was found that adhesions between the sheath of the nerve itself and the nerve substance were not infrequent in sciatica cases and that relief of the pain was very marked after these adhesions were broken up. Unfortunately a recurrence of the symptoms took place not infrequently in a few months, because of the re-formation of the adhesions.

Dr. Hunt, in closing the discussion, said that syphilis seems to be excluded in the cases, since there was no inflammatory reaction and no round cells or epitheloid cells such as are always found in syphilitic processes. The case was typical clinically of sciatica as it is ordinarily seen and there seems no reason to think that it was an anomalous type that was encountered.

Treatment of Acne.—Dr. George T. Jackson said that there are three indications for the treatment of acne. The first is to improve the condition of the skin, the second is to remove the bacteria that may be present and the third is to keep the skin surface aseptic as far as possible. The first indication can be best met by forgetting for the moment that there is any disease of the skin and correcting all other diseases that may be present. This means that all hygienic precautions must be observed and care taken of all the functions of the body. For the removal of the bacteria Dr. Jackson has found the curette and the acne lancet of special importance. Where there are many lesions, they should be removed by direct curetting two or three times a week. All deep-seated lesions should be opened with the acne lancet. This little instrument is better than the ordinary lancet because it possesses a shoulder which prevents it from sinking too deeply and thus giving rise to scars. Where acne lesions have not come to a head, slight pressure upon them brings out a white point. It is into this that the lancet should be plunged.

Local Drug Treatment.—Dr. Jackson considers that lotions are better than ointments in the treatment of acne, because the skin is already more greasy than it should be in these cases. He has found that sulphur is the best remedy and the lotio alba gives excellent satisfaction. In cases where there is much tendency to seborrhea, a resorcin wash is employed until the skin is shiny and then zinc oxide used to lessen the irritation. Dr. Jackson has found that certain forms of sulphur soap can be employed with decided advantage. At first the simple washing is enough but later the lather may be left on for some time.

The X-rays in Acne.—Some physicians have employed the X-rays for the treatment of acne, but the condition scarcely seems serious enough to justify the employment of so powerful an agent. One result of the use of the X-rays in certain cases has been the development of abnormally dry skin evidently with the development of an atrophy of certain portions of the true skin. Whenever the X-rays are employed, it must be with great care and only to the production of a slight burn, if even to this extent.

Colds and Grippe in 1904 and 1905.—The discussion of this subject was opened by Dr. James J. Walsh, who said that while in certain parts of the country, notably in Chicago, there seems to have been a serious development of grippe, during the present season, this has not been so clear in New York City. Statistics of the incidents of grippe in New York are not easy to obtain. They may be assumed from the reported deaths from grippe, but as it is easy to understand, most cases of true influenza that terminate fatally do so because of some complication, and the death is reported under this complication rather than directly from grippe. In fact it is not clear that true influenza exists in anything like the amount that has been sometimes claimed. It is not easy to isolate the bacillus of influenza and in not a few cases of this disease that is supposed to occur, other micro-organisms are found, notably the *Micrococcus catarrhalis.*

Prevalence of Grippe.—Since the first great pandemic of influenza began at Bokhara, in Central Asia, about fifteen years ago, and gradually spread westward, it has been said that there were recurrences of the epidemic each year. It has been the rule to find that a severe almost universal epidemic always produced smaller epidemics for a number of succeeding years after the first. A consultation, however, of the statistics in the United States, will show, for most of the nineteenth century, at least this is true according to Hirsch, that grippe has been prevalent every year in some part of the country. It seems not unlikely that though it is supposed to be the old grippe epidemic holding over each year, the cases that occur are scarcely more than have been noted in years previous to the great epidemic.

Pneumonia and Influenza.—It has sometimes been said that the great increase in the death-rate from pneumonia in this country, especially in our cities, is due to the influence of the grippe in complicating such cases and preparing the soil for the pneumococcus. As a matter of fact, however, a careful analysis of the statistics for pneumonia, as made in the Section on Hygiene at the meeting of the American Medical Association last June, shows that the death-rate for pneumonia has only increased under five and over fifty-five. Some of this apparent increase then is due to the fact that the spread of a better knowledge of children's diseases, has led to the recognition of pneumonia in children which were formerly missed. Obscure causes of death such as convulsions are gradually disappearing, as the death-rate from pneumonia goes up. In the same way, the mortality from old age is decreasing while the mortality for pneumonia is increasing. Many people used to die of old age who now die of terminal pneumonia. It would be impossible to argue with regard to grippe from the pneumonia death-rate.

Climatic Conditions in Grippe.—It has often been said that influenza is likely to be especially prevalent during the winter time, but when there is much damp weather rather than cold weather. As a consequence of this, it is thought that our severe winter of last year did not favor the existence of grippe while certain portions of the present winter have been more favorable. A consultation of the mortality from grippe in the two years here in New York City, however, will not bear out this idea, for the influenza death-rate last year was as great as this. Toward the end of the winter, owing to the fact that resistive vitality had been lowered by the severe cold, a great many cases of respiratory diseases were reported and there was an increase in the death-rate from influenza, as there is from all kindred diseases.

Influenza Groups.—Dr. Walsh said that in the epidemic of grippe in recent years, cases of similar character of the disease have occurred in groups associated with one another. For instance, it is the rule to find that where several members of a family come down with grippe, they suffer from the same type of the disease, *i.e.*, if in the first case the symptoms are mainly respiratory, subsequent cases are likely to have their affection confined to the thorax. On the other hand, if digestive symptoms are marked in the first case, subsequent cases in the same group are likely to show the same character. It would seem as though different types of bacilli were at work, and that probably there are a series of diseases all grouped together under the generic name, grip or influenza, which need to be studied much more carefully than at present in order to realize their indication.

Pains in the Bones.—At the present time the main symptom on which the diagnosis of grippe is founded is the occurrence of pains in the bones. It is probable that this symptom is due to the fact that there is an infectious agent in the blood destroying red blood corpuscles, and so making a special call upon the blood-making organs in the red marrow of the bone. It is not unlikely even that the bacilli themselves are directly irritative to the blood-making organs. It is in the flat bones of the pelvis and the skull, the characteristic headache and backache, and in the ends of the long bones, that the painful conditions are noted. Needless to say, this does not necessarily mean that the influenza bacillus is at work. Any infectious agent that will set up an irritative condition of the bone marrow will cause the pain complained of, hence the necessity for not considering that this symptom is at all pathognomic. With regard to the depression afterward the same may well be true, and there may be several forms of disease due to different micro-organisms at work.

Prevalence of Influenza Bacilli.—Dr. William H. Parks, in opening the discussion, said that influenza bacilli are present in a great many cases of catarrhal affections in our climate. During the winter season particularly is this true. More of them are found in January and February than in other months. The occurrence of the disease seems to be due to an increase of virulence, or a lowering of the resistive vitality of the patient, for the bacilli may be found even in those not suffering primary symptoms. Occasionally, perhaps, an association of different bacilli makes inoculation more easy. It is impossible to decide, however, whether there may not be a number of other bacteria grouped as influenza bacilli, because of morphological characteristics, yet without possessing true virulence. It is not impossible that once the disease has begun and passed through several persons the bacilli gain in virulence, and so become capable of affecting hitherto immune individuals.

Bacteria of Respiratory Affections.—Dr. T. W. Hastings said that in a large number of cases diagnosed as grippe he had found the *Micrococcus catarrhalis* to be the active agent. In not a few cases Friedländer's bacillus was also found. Some of the bacilli that seemed to be influenza bacilli proved later to be anomalous form of the *Bacillus pyocyaneus.* The most important bacillus in the winter time seems to be the *Micrococcus catarrhalis*, which in certain ways resemble the gonococcus or Weichselbaum's bacillus of epidemic cerebrospinal meningitis. This micrococcus, described also by Pfeiffer,

has been found producing conjunctivitis, vaginitis, bronchopneumonia, and certain cases of croup that were not diphtheritic. It occurs very commonly in the nose, and can only be recognized by careful culture methods.

Influenza Bacillus in the Eye.—Dr. Arnold Knapp said that in certain cases of conjunctivitis he had found the influenza bacillus in pure culture. In one case, in an infant, it produced a very severe form of membranous conjunctivitis, with perforation of the cornea. In this case it was not unlike the pneumococcus, or the diphtheria bacillus. A Vienna observer found that a form of trachoma was due to the influenza bacillus. In order to obtain the true influenza bacillus for purposes of comparison, Dr Knapp had to examine many cases of reported influenza in the hospitals. In only eight out of 120 supposed cases could the influenza bacillus be found Cultures of it grow well only where there is a certain amount of hemoglobin, which would seem to confirm Dr. Walsh's suggestion of the possibility of the bacillus having a special affinity for the blood-making organs, and hence producing the characteristic pains in the bones. This bacillis is found in otitis cases, as a rule, only where blebs containing bloody serum are present. The sequelæ of influenza affections of the eye are often very serious. Inflammation of the optic nerve may occur in the form of retrobulbar neuritis, producing central scotomata. At times distinct lines may be seen around the macula. Needless to say the prognosis of these cases is very grave.

Low Fever.—Dr. Warren Coleman said that the cases of grippe that have been under his observation this year have run their course with low fever not infrequently. In one recent case the temperature did not rise above 101° F., yet the fever was not broken for three weeks, in spite of treatment. The depression in these cases is beyond all expectation. In some of these low grade cases there are distinct disturbances of the cardiac rhythm. A very rapid heart is uncommon, and may last for some time into convalescence. Some of the cases have begun with distinct eruptions, at first erythematous, and then more urticarial in character, with prominent wheals. In these cases there is a distinct tendency to vasomotor instability.

Careless Diagnosis.—Dr. L. A. Connor said that most of the cases called influenza are undoubtedly ordinary catarrhal colds, which it has become the fad to speak of as grippy. In a number of cases in which microscopical examinations were made for the bacillus, the only case in which it was found was one where its presence had not been suspected. It would be a blessing if the term "grippe" were abandoned. It is applied now to every form of affection that occurs as the result of cold weather, from cold in one nostril to terminal pulmonary tuberculosis. Grippe is a soothing diagnosis to make. It prepares the family for the worst at once. Any number of complications may occur, and the doctor can scarcely be held responsible. It would be much better if the affections seen were called by proper descriptive names, laryngitis, pharyngitis, and bronchitis.

Nervous Sequelæ.—Dr. B. Sachs said that undoubtedly there has been some specially virulent infectious agent at work during the past fifteen years, the severe sequelæ of whose actions have been observed in the nervous system. These were much more severe twelve to fifteen years ago, when encephalitis and basilar meningitis were not infrequent. In more recent time there has been a lower grade of infection, and the peripheral nerves have suffered more. This problem of peripheral neuritis, due to influenza, sometimes makes a very serious diagnostic condition. A facial palsy, for instance, due to influenza may occur, and brachial neuritis is not uncommon.

Otologic Complications.—Dr. E. B. Dench said that influenza during the present winter has shown a distinct tendency to invade the ear more frequently than usual. The invasion is often sudden, accompanied by pain in the ear and some redness and bulging of the drum may be seen. In such cases an early myringotomy is necessary. Not infrequently mastoid tenderness is discovered early, and requires that the patient be carefully watched. The appearance of such tenderness must not be the signal for operating at once, since free drainage of the tympanic cavity may relieve the symptoms. Frequent irrigation with warm antiseptic solution seems to be the best treatment Dr. Dench has found no special good in the use of the ice-bag nor the cold coil, and, indeed, these only mask the symptoms. As a rule the symptoms abate within twenty-four hours after the incision of the drum membrane. In cases where spontaneous rupture of the drum has taken place, three incisions may have to be made in order to secure good drainage. Whenever there is pus in the mastoid it must be operated upon early.

Grippe as a Substitute for Malaria.—Dr. Winters said that the term "grippe" is a godsend now that the public have grown tired of the term malaria. The diagnosis of grippe is made lightly, and covers a heap of indolence. Nothing is more difficult than to make a correct diagnosis of grippe. There is no single clinical symptom by which the disease can be recognized. The most important diagnostic method is the careful exclusion of other affections. This winter the disease has been unusually mild, and the tendency has been to exaggerate the significance of the affection. Dr. Winters has seen apparently grave symptoms of otitis with mastoid tenderness, yet all but one of the cases got relief and remained well without operation. In one case six physicians were present and ready for operation—one of them the uncle of the child—yet it was decided not to operate, and the child recovered. As much as possible children must be saved from the shock of operation. Children should be wrapped well in blankets, so as to induce a free perspiration, and given a little niter, and perhaps a little aconite. Phenacetin should never be administered to children.

Special Grippe Symptoms.—Dr. George Mannheimer called attention to the fact that certain symptoms have been picked out as characteristic of grippe. Of these a redness of the anterior pillars of the fauces is not uncommon. The strawberry tongue persists in influenza longer than in other febrile affections. Not infrequently there is an enlargement of the spleen. The most characteristic group of symptoms, however, is the combination of respirative and digestive disturbances, with sweating. The sequelæ of the disease are many, and certain forms of muscular rheumatism are especially likely to occur in connection with grippe, and then to recur afterward

Dr. Bell said that many forms of affections of the upper respiratory tract are likely to be called grippe when really definite affections of known nature are present, but unrecognized for the moment. Follicular tonsillitis and pharyngitis are taken for grippe

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, held February 3, 1905.

The President, Samuel Lloyd, M.D., in the Chair.

Chronic Osteomyelitis.—Dr. C. A. Elsberg presented a male patient, forty-one years of age, in whom there had occurred a chronic osteomyelitis in the upper portion of the shaft of the femur. He had been operated upon at least once in one of the other hospitals of the city. The condition was a very obstinate one and recourse was had to iodoform wax filling. A thoroughly healed scar appeared at the site of operation beneath which could be felt a resisting mass; the remains of the unabsorbed iodiform filling.

Dr. A. S. Taylor exhibited two cases in which facio-hypoglossal anastomosis had been done. He said that in the earlier part of this work he had experienced a great deal of difficulty in avoiding extensive traumatisms of the twelfth nerve. This was easily demonstrated to be of great extent by the character of the paralysis of the tongue immediately after operation. He said that, however, with the new instruments, which he had devised for the purpose, this injury to the twelfth could be made a negligible quantity and that there was no indication therefore for cutting this important nerve.

Three Stages in the Repair of the Seventh.—Dr. Taylor said that three stages could always be made out very clearly as the cases began to improve. The first evidence of improvement was to be noticed in the face when it was at repose, the expression during quiescence appearing nearly normal. The second stage of improvement was marked by an ability to retract the angle of the mouth on the injured side, and the third was characterized by a return of what might be called emotional symmetry. He showed a boy, about eight years of age, on whom he had operated fifteen months before. The results were very good indeed, but not by any means perfect. The closure of the eye on the affected side was complete except at the inner canthus.

Dr. Taylor exhibited another case, that of a young woman in which he had, by the aid of the new instruments, been able to entirely avoid injury to the twelfth. Although the operation was done but two weeks ago, there was no paralysis of the tongue, and as in the case of the boy, the scar was small and unobtrusive.

Dr. H. B. Moseley showed a case of cured traumatic keloid of the face. This keloid as in the case of all his other subjects, had been operated upon repeatedly and the region had been skin grafted by competent operators. It had yielded to twelve months continued and severe treatment by the X-ray. The results were admirable.

Dr. H. P. Moseley showed a keloid of the anterior chest wall which had also been subjected to repeated removals and skin grafting. It had been cured after repeated exposure to the rays.

Dr. H. P. Moseley showed a cured keloid occurring in the neck. The lesion had been the result of an operation for a boil. It had been cut out three times and had eventually yielded to 90 exposures of the X-ray.

Dr. L. P. Clark opened the discussion of Dr. Taylor's paper. He said that the objection which had been made to lateral implantation of the seventh nerve into the twelfth, had been shown experimentally to be purely theoretical. These objections had been based upon the belief that too much work, by this anastomosis, would be put upon the nucleus of the twelfth. This nucleus had, however, been shown to be quite capable of doing the work of both nerves, and it was not surprising that it should be, for it was the largest nucleus in that region of the brain.

Value of the New Instrument.—The twelfth, therefore, if operated upon by the delicate and satisfactory instruments devised by Dr. Taylor, need not be injured to any extent, and the amount of vigor which was taken from it by the additional work cast upon its nucleus, was a negligible quantity. The seventh nerve furthermore, was not a true muscle of mastication and could readily be understood not to require the same amount of vigorous nerve impulse as was needed to drive such nerves, for example, as the second and third divisions of the fifth.

Dr. Howard Lilienthal said that he had understood, until hearing Dr. Taylor's report, that the eleventh nerve was to be preferred to the twelfth for facial anastomosis. The last of Dr. Taylor's cases, however, showed such successful preservation of the hypoglossal as demonstrated to him that with the use of the new instruments, this nerve was probably to be preferred to the spinal accessory.

Dr. A. S. Taylor said that the criticisms upon the use of the twelfth became very pertinent if use were made of it low down in the neck, as he understood to be the case in Fraser's operation. In that event the nerve has become so attenuated that it must be cut in order to complete the anastomosis; higher up in the neck, however, close to the petrous portion of the temporal bone, the nerve trunk is of substantial thickness and the anastomosis can be done without apparent injury.

Disadvantages of Eleventh.—One disadvantage of using the eleventh, which he said was not only theoretical, but, in some cases at least, real, was the convulsion of the patient by associated movements in the shoulder. These are very hard to disassociate and even after months are apt, especially under emotional conditions, to be manifest to a very disagreeable extent. Another reason for using the twelfth rather than the eleventh, the speaker considered to lie in the fact that the centers of the seventh and twelfth are nearer together than the seventh and the eleventh. This seems practically to result in a saving of time for the patient, because after all anastomotic operations education has to be begun as from infancy up.

Education of the Centers.—The cortical centers must be taught to operate new sets of muscles. A further reason for using the twelfth instead of the eleventh lay in the fact that if correlated movements did occur, which, indeed, had been noted, the terminations of the two nerves were closely associated with each other and one of them, the twelfth, supplied an organ which was in great part hidden within the mouth. Therefore they could not possibly be so noticeable as correlated movements occurring between areas widely separated as in the case of the termination of the seventh and the eleventh nerves.

Dr. Erdmann cited a case upon which he had operated about a year ago. He utilized the eleventh instead of the twelfth. Although there was for a time after operation a certain amount of motion of the shoulder coordinated with that of the face, this had passed away in relatively short time and the result he believed to be somewhat better than in the patient shown by Dr Taylor.

Treatment of Chronic Osteomyelitis and Chronic Bone Cavities, by the Iodoform Wax Filling.—Dr. Charles A. Elsberg said that the need of obliterating cavities occurring after ordinary abscesses in the soft tissues was, owing to the character of the yielding walls

of such cavities, a relatively rare occurrence. Not so, however, with bone cavities. Months of treatment and innumerable dressings become necessary for the treatment of cavities of the hard parts. A vast number of technics, many of them very ingenious, have been tried, —the skin flap inversion method and Schede's healing under moist blood clot being among the number. Recently, from Vienna, had come the suggestion of the iodoform wax treatment. The method there employed was to thoroughly cleanse the cavity and swab it out with two per cent. formaldehyde. The percentage of iodoform in mixtures used at Vienna averaged about 60 per cent., the spermacetti and the oils being arranged in such quantity that the mass, when poured in, would take from two to three minutes to harden. As in the case of paraffin injections elsewhere in the body, this mass can be shown to be slowly absorbed as the tissue grows in, and the observations of it under the X-rays greatly facilitate it by the presence of iodoform which throws a most excellent shadow. The all-important point in the technic is that every particle of decayed bone must be removed and the part must be made as dry as possible. Having found that a simple pouring of the melted mass into the cavity does not suffice to fill all its interstices, the author recently resorted to the plan of pouring the wax into cold water for a moment and then pushing it by hand or by an instrument, much as a dentist would fill a tooth, into the ramifications of the bone tissue. He has modified the technic further in that he uses but 20 per cent. of iodoform instead of 60 per cent. He has also utilized paraffin instead of wax and oil. The results have not been as good as those reported from Moorhof's clinic at Vienna, but sufficiently encouraging to warrant further experimentation with the technic. Even if it fails to give the needed union, the operation is certain to stimulate granulations, to cleanse the part and to relieve the pain of numerous dressings.

Dr. Virgil P. Gibney, in opening the discussion of this paper, said that he had never used wax, but had often employed powdered iodoform. He had two successful cases and several failures, which, after hearing Dr. Elsberg's paper, he was convinced were due to a failure to thoroughly cleanse the parts.

Dr. Howard Lilienthal said that the author was not sufficiently enthusiastic about the results which had been obtained in the 15 cases reported. In the speaker's opinion, they had been more than good. The cessation of discharge in itself, he said, was almost enough to warrant the operation, which was free from danger. He considered the technic a great advance over the older method of packing, but neither so simple nor so sure as the filling of a tooth.

Dr. A. V. Moschcowitz said that a four per cent. solution of agar, if mixed with iodoform, might be used advantageously to fill the cavities, because such a combination would penetrate further into the interstices of the bone; complete hemostasis in this case being unnecessary.

Dr. Elsberg, in closing the discussion, said that agar had been tried. He felt very certain that the wax was better and that it should be shoved in, adranalin having been used before-hand to control oozing.

Treatment of Keloid by the X-ray.—Dr. Henry P. Moseley said that the treatment of keloid by incision had been shown to be almost universally a failure. While the X-ray, he said, was not without numerous objections, he considered that a study of the cases presented demonstrated that it was the most potent agent for the treatment of this obstinate and fortunately very rare condition. He said that so far there had been no recurrence in the cases which had been treated at the Presbyterian Hospital. He had concluded that in order to get results, the part must be severely burnt.

Dr. A. L. Fisk, in opening the discussion, said that very few cases had been reported. The literature recording but twelve, all of these having occurred in post-operative keloid. Such keloids, it is true, tend to disappear spontaneously, but undoubtedly the X-ray hastens the process.

Dr. C. W. Allen said that a distinction should be made between true and surgical keloids. He had found the X-rays useful in the disfiguring keloid of facial syphilis. He disagreed with the reader of the paper in contending that a dermatitis need not always be produced in order to make the keloid disappear.

Dr. Robert P. Morris reported two cases, both of which had been subjected to operation by eminent surgeons, with a failure in each case, until recourse was had to the X-ray.

Dr. Moseley, in closing, said that he was certain that in order to get results, a burn must be made. Furthermore, his best results have come from the use of a low vacuum tube. This should be used for all superficial troubles.

The Present Status of Blood Examination in Surgical Diagnosis.—Dr. F. E. Sondern said that great changes had taken place in the relation of blood examination to surgical diagnosis in the past twelve years. He reviewed the extensive literature of the subject up to the present time and then called attention to the fact that almost all the older observations were based upon the extent and rate of development of the leucocytosis. This misconception had given an opportunity to a great many men prominent as clinicians, to cast odium upon the value of the blood count as a diagnostic surgical sign. These adverse opinions were based chiefly on two points, viz., the absence of the leucocytosis in some cases in which pus was present, and the presence of pus in a reasonably large number of cases having a low leucocyte count. As a result of a great number of blood examinations made in surgical diseases, the author had been impressed by the fact that the differential count offered a far better guide to the status of an inflammatory process, and one which was not influenced to any extensive degree by bodily resistance, than the simple degree of leucocytosis. A study of about 5,000 blood specimens had yielded an average percentage of 62 for the polymorphonuclear. While it is true that the percentage of these cells varies somewhat in health as well as in the different stages of bodily resistance, these variations the author held to be within narrow limits.

Three Distinct Blood Pictures.—The author finds three distinct pictures in inflammatory lesion. First, a relative percentage of polynuclear cells below 70 with an inflammatory leucocytosis of any degree excludes the presence of gangrene or pus, and usually indicates good resistance. Second, an increased relative percentage of polynuclear cells with little or no leucocytosis is still an absolute indication of the inflammatory process and the percentage is a direct guide to the severity of the infection. The author has never observed a case of pus or gangrene with a polynuclear percentage below 70. In adults these conditions are decidedly uncommon with less than 80 per cent., and the probability of their presence increases with the percentage. Ninety per cent. of polynuclear cells indicate profound cachexia, while the prognosis for recovery is extremely bad in all cases over 94 per cent. Third, an increased relative percentage of polynuclear cells with a decided inflammatory leucocytosis.

Relation of Leucocytosis to Resistance.—The old maxim was, "Good resistance, marked leucocytosis; poor resistance, little or none." A. M. Holmes (*Jour. A. M. A.*, January 26, 1905) judges bodily resistance by small lymphocyte count. The author, however, believes the percentage of polynuclear cells is the best indicator of this condition.

Iodophilia a Guide to the Inflammatory Process.—Locke has obtained interesting results from this method. In the author's hands it has not seemed as reliable as the polynuclear percentage.

Dr. Edward Quintard, in opening the discussion, said that procrastinating medicine had undoubtedly killed more people than rash surgery. Despite this fact he considered that the employment of such a valuable diagnostic adjunct as had been described could but prove useful to the surgeon. He said that in his work upon the stomach, he had found that the polymorphonuclear differential count had proved valueless as a diagnostic aid in carcinoma.

Dr. Francis C. Wood agreed very cordially with the reader of the paper as to the value of the differential polynuclear count. He cited the case of a hospital interne whose life had been undoubtedly saved by its employment, a gangrenous appendix having been recognized through the agency of the differential, when, clinically it gave almost no symptoms whatsoever. Dr. Sondern, in closing, said that the blood picture was of no value whatsoever in establishing the diagnosis in carcinoma of the stomach.

CHICAGO SURGICAL SOCIETY.

Regular Meeting, held March 6, 1905.

The President, L. L. McArthur, M.D., in the Chair.

Dermoid Cyst of Lung.—Dr. Nicholas Senn reported a case of dermoid cyst of the lung, saying that thus far there are only sixteen cases on record. This is an unusual and very rare surgical affection. The patient, C. R., a male, aged twenty-three years, American, unmarried, a railroad man by occupation, entered the out-patient department of the University Hospital, Michigan, July 19, 1904. The case was very carefully studied there, and a history of it very accurately reported by the attendants at the clinic, and particularly by Dr. Roger S. Morris, to whom Dr. Senn was indebted for a complete history of the case. When the patient entered the Presbyterian Hospital, Chicago, the speaker had no idea that the case had been so thoroughly studied. The history of the case as related by Dr. Morris, is as follows: "The patient entered the University Hospital, July 19, 1904, when I first saw him with Dr. Ellis. From certain points in the history, which will appear presently, together with the result of the physical examination, I diagnosed the condition as probable dermoid cyst of the thorax, though unaware at the time of similar cases. The patient, a resident of a neighboring town, was unable to remain at this time, but was advised to return. This he did. On July 27, 1904, he was admitted to the medical ward, and the following history was obtained: On admission the patient complained of cough, expectoration of large quantities of foul-smelling sputum, and hemorrhages from the lungs. *Family History.*—Father is living and well. Mother has had "stomach trouble" nearly all her life, but is in good health at present. The patient has two brothers and three sisters who are alive and well. An aunt on the father's side died of "hemorrhage of the lungs and dropsy;" nothing more definite is known of her case. Otherwise the family history is negative. *Personal History.*—As a child, the patient was very well. He had measles, chickenpox, and a mild attack of diphtheria or tonsillitis. In all instances recovery was uneventful. At the age of twelve the patient had a diarrhea which persisted for about a year. Since then the patient has enjoyed good health until the onset of the present trouble. *History of the Present Disease.*—About nine years ago (eight years, according to out-patient history), that is, about the time of puberty, the patient had a severe attack of pneumonia on the left side, followed by a feeling of tightness across the chest and pain on breathing. The latter was localized to an area about the size of a hand in the precordial region. Prior to the attack of pneumonia the patient says he was struck over the heart by a drunken man, and ascribes the pneumonia which soon followed to the blow which he received. Between the time he was struck and the development of the pneumonia, he had severe neuralgic pains in the region of the heart and in the left shoulder. A year later the patient had another attack of pneumonia, which lasted about eight weeks. During a coughing fit, a large quantity of "pus" was coughed up at one time (over one quart). The "abscess" or "empyema" discharged three times in the next three or four days. The patient describes the so-called pus as a "yellow, semi-fluid material." After raising this material, the patient became much better, but has coughed and expectorated a good deal ever since. Four years ago the patient had a very severe hemorrhage from the lungs, and since then he has had one about every six months. The last one occurred just before the patient returned to the hospital. At times the hemorrhages amount to about one pint. During the last three years the patient has noticed a "rotten" odor to the sputum. In March, 1904, he went to Colorado for his health. He was examined by a physician, and told that he had empyema. Operation was advised. This the patient did not submit to. No tubercle bacilli were found in his sputum at this time. For some time the patient has coughed up hairs in his sputum; these are from one to six inches long. Since last March there has been some soreness over the right side of the chest. Expectoration is much more profuse when the patient is lying down. He has not lost weight.

Status Præsens, July 29, 1904.—Temperature has been normal since admission, respirations 20, pulse 72, regular, of fair size and tension. No palpable thickening of the arteries. Patient looks very well nourished. Active dorsal position. Mind clear. Build rather short and stocky; strong frame; panniculus fair. Muscles well developed and rather soft. The skin is of good color, smooth, dry, and elastic. No edema of ankles. There are no stiff joints. Lymph glands about left clavicle and behind left sternocleidomastoid are slightly enlarged; otherwise negative. Expression is negative. Pupils are equal, react well; sclerotics are clear, slightly bluish. Conjunctivæ and lips are of good color. Teeth are in fairly good repair. The tongue is large, clean and moist. Examination of neck negative. Thorax is well formed, rather large. The left side seems slightly fuller than the right. The epigastric angle is about a right angle. Expansion is rather small, slightly less on the left side, especially on deep breathing. The difference is more noticeable in the lower part of the thorax. The clavicles are equally prominent. On percussion the apices are of equal height, about one and one-eighth inch above the clavicles. Above the second rib the percussion note is the same on the two sides. Below this level the note is somewhat hyperresonant on the right, with relative dulness throughout the left

front, the upper border of the relatively dull area sloping downward and backward into the left axilla. Traube's space is clear. There is no absolute liver dulness. The lung liver border is on the sixth rib in the right nipple line; it extends straight around. The lung descends to the seventh rib on deep inspiration. Auscultation above the right clavicle gives rather harsh vesicular breathing, with fairly high-pitched sibilant râles on inspiration; below the clavicle throughout the right side there is moderately strong vesicular with no adventitious sounds. Above the left clavicle the breath sounds are obscured by sonorous rhonchi, which are heard both on inspiration and on expiration. Below the left clavicle there is harsh vesicular accompanied by dry râles of medium pitch, the vibrations of which can be felt on palpation. Below a line drawn from the anterior axillary fold to the left nipple the vesicular is very weak, and toward the end of inspiration a few crepitant râles are heard. The ausculted spoken voice is slightly weakened between the second and fourth ribs on the left; vocal fremitus unaltered here. Posteriorly, the apices are of equal height on percussion. Below the level of the spine of the eighth dorsal vertebra there is relative dulness on the left side; this is continuous with that previously described in the axilla. In other respects percussion of the back is negative. The upper border of relative dulness does not move with change in position of the patient. Auscultation reveals fair vesicular throughout the right back and on the left back down to the dull area, where the vesicular is weak and distant. Pectoral fremitus is slightly weaker on the left side over the same area. Auscultation of the spoken voice is negative behind. The apex of the heart is best felt in the fourth intercostal space in the nipple line. At the beginning of the examination a pulsation was seen on the second and third interspaces, which was forcible enough to be palpated. Absolute heart dulness begins on the fourth rib and extends outward to the apex: on the right it extends to the left sternal line. The relative heart dulness cannot be separated from that obtained over the left lung. The heart sounds are moderately strong and clear. The second pulmonic is reduplicated and accentuated. Abdomen is on a level with the ribs. It looks natural. The walls are quite resistant, making palpation difficult. Spleen and liver are not felt. Percussion is negative. Leucocyte count, 9,256 on July 27, 1904. Urine examination was negative. Sputum was examined July 31, 1904. The color was whitish-gray. Sputum had a foul odor, like that of "bad" eggs. It separated into three layers. No tubercle bacilli were found; no elastic tissue. Later a hair was found in the sputum. Fluoroscopic examination shows a slight shadow throughout the left side above. Below the level of the eighth dorsal spine and extending to about the level of the eleventh dorsal there is a diffuse dark shadow, as dark as that from the liver. The entire right side is clear. A skiagraph was taken; unfortunately the negative was poor."

Clinical History.—Dr. Senn stated that this clinical history was very full and accurate, and corresponded exactly with what he had found on careful examination of the patient repeatedly after his entrance to the Presbyterian Hospital. The patient coughed up during his residence in the hospital for a number of weeks, six or eight hairs. These hairs were very thin, lighter in color than the hair of the scalp, and varied in length from one to six inches. Sometimes, when patient expectorated these hairs, he felt a certain sensation which he referred to the base of the heart. Expectoration, at times, had been very copious and fetid. The patient's general condition was excellent. There was no wasting, no cachexia, hence any suspicion of tuberculosis could be abandoned without giving the chest a careful examination. He had made use of the X-ray in this case, and the skiagraph exhibited corresponded to what Dr. Morris had described in the clinical history. From the clinical history, the character of the sputum, the general condition of the patient, there was no difficulty in making an absolute diagnosis of dermoid cyst communicating with the lung. He resorted to a surgical operation for the purpose of exposing, if possible, and removing the lining membrane of the dermoid cyst. Clinical records showed at the present time almost invariably that these cysts had their location in the anterior mediastinum at a point corresponding with the location of the thymus gland. This was their favorite primary location. He therefore aimed in operating upon this patient to expose that portion of the mediastinum which is most frequently the seat of dermoids of the lung. He made a T-shaped incision, which remained well-defined by the scar which followed as soon as the wounds had healed, largely by primary intention. He made a transverse incision directly over the manubrium, and a vertical incision over the center of the sternum. As he wanted to trephine the manubrium at a point corresponding with the location of the thymus gland, he made another or second opening two inches lower down, after reflecting the cutaneous flap and periosteum, which were separated from the sternum, and united these trephined openings by the use of a chisel, thus making an opening more than two inches in length in its vertical diameter, exposing freely that part of the anterior mediastinum which was generally the seat of dermoid cysts. The moment he opened up the anterior mediastinum by cutting through the posterior layer of the periosteum, air entered forcibly. Hemorrhage was quite profuse. He enlarged the opening to correspond with the size of the trephine openings, and this exposed freely the anterior mediastinum. Owing to profuse hemorrhage, he packed the large wound with iodoform gauze, and allowed the gauze tampon to remain for five or six days, when it was removed, and when he anticipated, in all probability, he would find the remains of the dermoid cyst in the expected location. In this, however, he was disappointed. In removing the tampon he found that the entire part of the anterior medastinum which was exposed lined fairly well with granulations. He proceeded to explore the floor of the wound with the probe, but no trace of the dermoid cyst could be found. The operation had not influenced the clinical course of the disease. Before resorting to operative measures, and knowing nothing about the previous history of the case, for the purpose of locating, if possible, the dermoid cyst accurately, he resorted to exploratory punctures. He found, as did Dr. Morris, an area of dulness corresponding with the upper segment of the sternum and at the base of the heart. He explored about an inch and a half from the left margin of the sternum and a little above the base of the heart to the depth of three or four inches, resorting to aspiration, gradually withdrawing the needle, but the result was negative. He found likewise a limited area of dulness which corresponded with the intrascapular region, that is, between the spinal margin of the scapula and the transverse process of the spine. In this locality he punctured, but with a similar negative result. The patient coughed now about the same as he did before the operation, so that the question arose as to what was to be done in the future. He exhibited the patient with a view of asking the advice of the members of the Chicago Surgical Society as to

the course to be pursued in the future. He could do nothing more with the anterior mediastinum. The patient had a slight area of dulness extending over the base of the heart, with a similar area of dulness on the posterior surface of the lung. He thought he had to deal here with an exceptional case. In nearly all, if not all, cases of dermoid cyst of the lung it was found to take its origin in a location corresponding with the thymus gland. That part of the mediastinum had been thoroughly explored. Nothing was to be gained by repeating the operation in that locality. He took particular care to use a probe in all directions in search for a possible sinus communicating with the supposed original seat of the disease. The question arose now, should he resort to costal resection at a point to which the patient referred his difficulty, namely, above the base of the heart, or should be, in view of the fact that distinct physical evidence of pulmonary complications, or, at least, pleural thickening over the posterior aspect of the chest had been found, operate in that locality? He had kept the wound open for a number of weeks with a view to studying repeatedly the condition of the anterior mediastinum, which was exposed by the operation. The arch of the aorta could be seen in the lower part of the wound. The operation wound had now completely healed, yet the patient was in the same condition as he was before operation.

Dr. Senn passed around some of the hairs which the patient has expectorated at irregular intervals. One of the hairs measured six inches in length.

He also reported cases of (1) echinococcus cyst of the lung; exploratory puncture; rupture of cyst. (2) Dentigerous tumor of superior maxilla. (3) Ligation of internal and excision of external carotids for malignant disease. (4) Disarticulation at the hip-joint for sarcoma of femur and tubercular endovaginitis. (5) Extensive plastic of the face after operation for carcinoma of the orbit, nose and face. (6) Rectoplasty for extensive traumatic defect. (7) Scar carcinoma in the region of the great trochanter. (8) Fracture of humerus with posterior dislocation of upper fragment. (9) Secondary suture of ulnar nerve after gunshot injury.

Surgical Treatment of Chronic Mucomembranous and Ulcerative Colitis; with Special Reference to Technic.—Dr. J. E. Summers, of Omaha, Neb., read a paper on this subject, by invitation. The author first discussed chronic primary colitis; then primary membranous colitis and ulcerative colitis, and reported cases. After referring to the work of Keith, W. Hale White, Deaver, MacEwen, Cannon and Lane, the author stated that in order to cope successfully with the different kinds of colitis the surgeon must, in so far as possible, be able to differentiate the cases and apply the surgical procedure to fit the cause. This is rather new surgery, but has a field of usefulness. Any form of colitis which has resisted careful medical treatment must be studied with a view of determining the cause and the reasons for the persistence of the cause. For surgical convenience he recognizes three kinds of colitis: (1) The inflammatory, due to the effect of some specific organism—an inflammatory disease commencing in and mostly confined to, the colon. (2) An inflammatory condition secondary to an inflammation or derangement of function of the vermiform appendix. (3) An inflammation induced by technical interference with the peristaltic, and more especially the antiperistaltic waves of the colon. The surgical treatment of colitis, if carried out in recognition of these causes, will be successful. To be successful, the type of operation must be selected with a view to meeting the pathology. It will not do to confine oneself in all cases to a right inguinal colotomy. This may have done for the class of cases for which it was first selected, but even in this class, which the author designates the bacteriological, the artificial valvular fistula operation suggested by Gibson, of New York, has many advantages, not the least being the annoyance of a large open fistula, and the inevitable loss of weight and strength which always follows the free external discharge of chyme as it comes direct from the ileocecal orifice. In his experience with the appendicular forms of colitis, there are two varieties—first, and most common, the explosive form, which is recognized in the first few hours by intense general abdominal pain, with tenderness over the appendix. In from six to twenty-four hours dysenteric symptoms develop, which may last some days, and then gradually subside or persist with moderate symptoms for several weeks. These attacks recur. The other form is of the kind described by Deaver. In the first kind the removal of the appendix is all that is required, as has been so in three of the author's cases. In the neurasthenic type of Deaver not only should the appendix be removed, but the Gibson cecal fistula ought to be established—the long-continued interference with cecal and colonic digestion by the abnormally functionating appendix has brought about changes in the mucosa of the colon that can only be cured by the rest and local treatment afforded through this fistula. If these simple means will not bring about a cessation of the discharges, and the impaired health which always accompanies them, then something further must be done. The colon must, in greater or less part, be excluded from the process of intestinal digestion and the function established gradually by the small intestines and the remaining portion of the colon. Operations for exclusion have undergone a remarkable evolution.

Drainage in Diffuse Septic Peritonitis.—Dr. Van Buren Knott, of Sioux City, Iowa, read a paper, by invitation, on this subject, in which he drew the following conclusions: (1) Operations for diffuse septic peritonitis should be made as quickly and with as little manipulation as is compatible with thoroughness. (2) Evisceration, partial or complete, greatly increases shock and the prospects of a fatal result. (3) The general use of clean hot water will most thoroughly cleanse the infected cavity with the least traumatism. (4) Drainage is simplified by collecting the peritoneal fluid at one point where drains may be easily placed. The elevated head and trunk posture followed by the gravitation of fluid to the lower pelvis best accomplishes this. (5) Results following the surgical treatment of diffuse septic peritonitis will be improved should each individual operator adopt some definite form of procedure in such cases which, being well understood by operator and assistants, may be methodically, speedily and thoroughly carried out.

Exclusion of Portions of the Intestine.—Dr. M. L. Harris, in discussing these two papers, said his experience as to exclusion of portions of the intestine had always been limited to exclusion with drainage into the intestine. He has resorted to this method in several cases in which the cecum and ascending colon were involved, and always with success. He has always made use of the method of dividing the ileum and transplanting it into some portion of the colon distant to the trouble which he sought to relieve. The colon was always left free, so that it could drain. He believes this is an essential feature, and thinks that complete exclusion of any portion of the intestinal tract should never be undertaken.

Exclusion of the Bowel.—Dr. Jacob Frank said, with reference to exclusion of the bowel, in some of the cases reported before the society, it was demonstrated that in that part of the bowel which was excluded there were masses formed from the secretions or excretions from the mucous membrane. These masses consisted of small balls of cheesy substance, filling up the excluded bowel. He does not think it is safe to close up both ends, as he has demonstrated this in dogs. He has specimens at home of these cheesy masses which he intended to exhibit at a future meeting of the society. As to Dr. Knott's paper, he had tried the method mentioned by him, and in two cases of diffuse septic peritonitis he filled the abdomen with salt solution, put the patients in the Fowler position, and used glass drainage tubes, setting the patients up in bed with a backrest, and both recovered.

Treatment of Septic Peritonitis.—Dr. Daniel N. Eisendrath showed the photograph of an apparatus which has been in use in the Michael Reese Hospital for the past two or three years for the treatment of cases of diffuse septic peritonitis. This apparatus has advantages over using tables, chairs, etc., as one can more accurately get the Fowler position. It is an advantage over propping up of the patient in bed, for those who have had experience with such patients know that in their weakened condition they would slip down. About a year ago, when he began to use the Fowler position systematically and to flush cases of diffuse septic peritonitis thoroughly with hot salt solution, using three to four gallons in each case, he changed his mortality from 100 per cent. practically to a large per cent. of recoveries. He cited three cases of diffuse septic peritonitis that had recovered from this treatment.

Dr. Alexander Hugh Ferguson said that in a spreading inflammation of the peritoneum one should not forget where the focus of the inflammation was when he begins to drain. The Fowler position, which has been so much lauded and recommended, should not supplant every means of drainage of the abdominal cavity. He mentioned three positions from which pus emanated that should not be drained by the Fowler position.

Dr. Knott, in closing the discussion on his part, said, with reference to the remarks made by Dr. Frank, he believes in the long-run Dr. Frank would secure better results, afford more comfort to his patients, with less tendency to fecal fistula, by the use of soft rubber tubes than by the use of glass tubes.

Dr. Summers, in closing the discussion, said that his experience had been limited to eight operative cases. He did not know that Dr. Harris had been doing the operation of intestinal exclusion with drainage into the intestine. He was not aware of it, because Dr. Harris had not published his work. With reference to Dr. Knott's paper, he would say that Dr. Knott was so thoroughly convinced of the utility of the plan advocated in treating cases of diffuse peritonitis, that he operated upon his own son, eighteen hours after an operation for perforation appendicitis by another surgeon. Dr. Knott had himself operated in the absence of a colleague, making extra median incision, and with toilet and drainage established, saved the boy's life.

BOOK REVIEWS.

German-English Medical Dictionary. By Hugo Lang, B.R. Edited and completed by Bertram Abrahams, M.B., B.Sc., F.R.C.P. P. Blakiston's Son & Co., Philadelphia.

This substantial volume fills a long-felt want for the English-speaking members of the profession of medicine, and the author has handled the difficult question of the genders sensibly. As regards the mute letters, both spellings are given where the lack of the older form might occasion any uncertainty. The bulk of the book is commendably limited by the omission of words spelled identically in the two languages, and a large number of terms used in chemistry, biology and pathology are included. It is, furthermore, a good piece of book making, in remarkable readable type and strong and tasteful binding.

Text-Book of Insanity Based on Clinical Observations. By Dr. R. von Krafft-Ebing, late Professor of Psychiatry and Nervous Diseases in the University of Vienna. Authorized translation from the latest German edition by Charles Gilbert Chaddock, M.D., Professor of Diseases of the Nervous System in the Marion-Sims-Beaumont College of Medicine, Medical Department of St. Louis University, St. Louis, Mo., etc. F. A. Davis Company, Philadelphia.

Dr. Chaddock has excellently performed a much-needed service in giving to readers of English so careful and adequate a translation of Krafft-Ebing's great work, which has remained a leading German text-book on insanity, although the author's strong bent toward psychologic explanation has fallen somewhat into disfavor in these later days during the tremendous vogue of Krapelin. The facts of morbid psychology have never found a better clinical exposition than in this volume, which resulted from the minute and continued study of cases by an indefatigable and patient observer. His labors belong chiefly, or at least characteristically, to that period when the subject was undergoing minute analysis, and hence we find him distinguishing nine or ten forms of epileptic insanity and as many of paranoia. He also dwells to some length on those cases in which two or more forms of insanity in the same patient may run simultaneous courses, each undisturbed by the other. In spite of the fact that psychiatry has undergone considerable change and development, mainly in the direction of synthesis, since the publication of the first edition of Krafft-Ebing's text-book, in 1879, it still remains unparalleled in its minute and exhaustive descriptions of mental states related to bodily disease, and as such is invaluable to the student, especially to such as have enjoyed but limited opportunities for clinical observation in person.

Atlas and Epitome of General Pathologic Histology. By Dr. H. Dürck, of Munich. Edited, with additions, by Ludwig Hektoen, M.D., Professor of Pathology, Rush Medical College, in affiliation with the University of Chicago. W. B. Saunders & Company, Philadelphia, New York and London.

In placing this volume before the medical profession, the author reflects the latest and most generally accepted views concerned in circulatory disturbances, retrogressive metamorphoses, reparative processes and tumors.

As an epitome the text is adequate and consistent. As an atlas it is singularly elaborate and instructive. The plates, which are accurately represented, artistically executed and beautifully reproduced, are placed throughout the subject-matter with studied care.

The book can be recommended as a valuable adjunct in acquiring a better understanding of pathologic histology.

ETIOLOGY, DIAGNOSIS AND TREATMENT OF BENIGN STENOSIS OF THE PYLORUS.[1]

BY GEORGE EMERSON BREWER, M.D.,

OF NEW YORK.

IN response to an invitation from the President of this society, I shall present for your consideration and discussion this evening, a brief review of our present knowledge of the etiology, diagnosis and treatment of benign obstruction of the pylorus.

In accepting this invitation, I realize fully that I am addressing an audience made up largely of expert observers in this line of work. I also recognize the fact that my own experience in gastric surgery is a comparatively limited one. I may, therefore, be permitted to state at the outset that my reason for presenting this subject before this Society is not that I hope to enlighten its members by anything new or original, but simply to bring this important topic before you for your critical discussion, which cannot fail to be of value to myself as well as to the profession at large.

Although dilatation of the stomach due to pyloric stenosis has been known as a pathological entity for centuries and its association with vomiting, delayed and painful digestion recognized in certain instances, it was not until the latter part of the nineteenth century that its importance began to be appreciated, and the differentiation between the benign and malignant forms of the stenosis made.

In 1868, Victor Bros, in his Strassburg thesis, reviewed the subject of benign obstruction of the pylorus and gave a classical description of the symptomatology of a typical case of the disease due to gastric ulcer.

The following year Kussmaul began the use of the stomach tube in the treatment of this condition and led the way for his pupils, Von de Velden, Leube, Ewald, Boas and a host of others, who studied the effects of obstruction on the function of digestion, and furnished valuable data for diagnostic purposes in the estimation of the motility of the organ and the chemical analysis of the gastric contents.

The first effect of a moderate narrowing of the pylorus is obviously an increased peristaltic effort on the part of the muscular apparatus of the stomach, to propel the food into the duodenum. This in an otherwise healthy individual generally results in a compensatory hypertrophy of the gastric musculature, and while this compensation is maintained no untoward symptoms occur. Sooner or later, however, if the disease is progressive, this compensation fails and a certain quantity of the food is habitually retained in the stomach. As in the case of the urinary bladder, this inability of the viscus to empty itself gradually results in dilatation of the organ with atony of its muscular walls. Stagnation of the gastric contents results in fermentation—fermentation gives rise to the formation of acrid acids and gases, which in turn irritate the mucosa and eventually cause a subacute gastritis or catarrh of the stomach.

Relief to the overburdened and irritated stomach can only occur from vomiting. This takes place at first at infrequent intervals, later more regularly, and when the obstruction becomes practically complete, after each meal.

As the stenosis increases a progressively diminishing amount of food passes into the intestine, and as absorption of water from the stomach itself is practically *nil*, thirst, diminished secretion of urine, constipation and rapid emaciation occur. When the obstruction becomes complete, death from starvation is the inevitable result.

The foregoing description applies to a progressive stenosis resulting in complete obstruction. In certain instances, however, the disease advances up to a certain point and then becomes arrested. In these cases the symptoms will vary according to the degree of obstruction, and the muscular tone of the organ. In general it may be stated that a stomach which is unable completely to empty itself over night, will surely give rise to symptoms requiring treatment.

In considering the etiology of benign stenosis of the pylorus, we should, I think, follow the suggestion of Mayo, who maintains that lesions in the first two and a half inches of the duodenum should be included, as the pathological conditions producing stenosis in the portion of the duodenum above the papilla are practically identical with those of the pyloric region, and the resulting symptoms so similar that differential diagnosis is in most instances impossible except by exploratory incision.

The commonest cause of benign stenosis of the pylorus is undoubtedly ulcer. Gastric ulcer occurs at or near the pylorus with great frequency, most authorities agreeing that at least 75 per cent. of the lesions are found in this region. That duodenal ulcer is also of frequent occurrence is evident by the statistics of Mayo, who reports that the first portion of the duodenum was involved in 27 per cent. of his operated cases of ulcer.

A gastric or duodenal ulcer may produce a primary pyloric stenosis, either by the presence

[1] Read at the Annual Meeting of the American Gastro-Enterological Association, April 25, 1905.

of an acute inflammatory exudate in the surrounding tissues or at a later stage by marginal induration or cicatricial contraction. Not infrequently when the process involves the deeper tissues or where a minute perforation has occurred, a circumscribed or spreading peritonitis is developed, which, if recovery takes place, results in the formation of adhesions which give rise to stenosis from angulation or fixation of the pylorus to the other organs.

Obstruction of the pylorus by spasm, caused by the irritation of an ulcer in some other portion of the stomach is said to occur and to give rise to the same train of symptoms as organic stenosis, but as Stockton has pointed out, too much reliance must not be placed on this statement which at present rests only on an hypothetical basis.

Diseases of the gall-bladder are second in point of frequency in the causation of pyloric stenosis. The commonest lesion of the gall-bladder to produce this effect is cholecystitis with local peritonitis. This gives rise to secondary adhesions which produce angulation and fixation of the pylorus or duodenum in the same manner as the adhesions from a perforated ulcer.

Fistulous openings between the gall-bladder and stomach or duodenum may occur, as a result of suppurative cholecystitis. Through these openings large stones may occasionally pass into the intestine. The presence of these stones may, very rarely, give rise to obstruction, whereas the cicatricial contractions of the fistulous tract and the perigastric adhesions more frequently cause narrowing of the pylorus and duodenum.

A case illustrating the degree to which narrowing of the pylorus and duodenum may reach from such a condition is the following:

Case.—A man, fifty-four years of age, had numerous attacks of pain and tenderness in the right upper quadrant of the abdomen. Later he had gastric distress and vomiting. These symptoms increased rapidly in severity and he became emaciated, weak and anemic. When first seen by the writer he stated that he had lost fifty pounds in the previous two months. The abdomen was very much retracted and a tumor was felt in the pyloric region which did not move with respiration. Stomach enormously dilated, no free hydrochloric acid present; hemoglobin, 40 per cent.

On opening the abdomen, the gall-bladder, pylorus and duodenum were found fused together by dense adhesions. The gall-bladder was opened and found to contain a quantity of pus and seventeen stones. When these were removed, the examining finger passed through a narrow opening into a secondary cavity also containing numerous calculi. We at first thought we had to do with a double gall-bladder, but after a long and difficult dissection, it was found that the supposed accessory gall-bladder was in reality, a pouch formed by the first portion of the duodenum into which the suppurating gall-bladder had emptied. This cavity was separated above from the stomach and below from the second portion of the duodenum by two large, almost complete cicatricial strictures, each intimately associated with the inflammatory induration around the margin of the fistulous opening. On laying open this duodenal pouch thirty-six stones and a moderate amount of foul-smelling pus were evacuated. A pyloroplasty by the Finney method was performed, but the patient succumbed to the shock of the prolonged operation. In this case the occlusion had been practically complete for a number of weeks.

The presence of benign tumors at or near the pylorus, has occasionally been reported as giving rise to obstruction. The writer on one occasion found and removed a small adenoma from the anterior wall of the duodenum just above the papilla. Lipomata arising from the submucous layer of the stomach, near the pylorus, have occasionally been reported, some reaching a large size. Myomata papillomata and lymphadenomata have also been found but are exceedingly rare and as a rule too small to produce serious obstruction. A few instances are on record of a polypoid tumor with long pedicle, which would occasionally be carried into the pyloric orifice and produce intermittent occlusion.

More important than the preceding group are the hypertrophic stenosis. This condition has been described by a number of observers including Tilger, Boas, Habershon and Oettinger, and each has given it a different name. Practically all unite, however, in regarding the obstruction as one of hypertrophy and sclerosis of the muscular and submucous coats, causing great narrowing and rigidity of the orifice. The pyloric region is often so thickened that a distinct tumor may be felt through the abdominal wall.

Three varieties of the affection have been described: First, the congenital stenosis, in which there is thickening of the submucous coat with hypertrophy of the circular and longitudinal muscular fibers, but without lesion of the mucous membrane, obviously a non-inflammatory condition; second, the adult type which appears to follow a chronic gastritis in which the mucous and submucous coats of the entire stomach are involved, giving rise to a cirrhosis of the organ, and third, where the disease seems limited to the pyloric region. In the cirrhotic variety the capacity of the stomach is greatly reduced and dilatation is impossible, while in the third variety, dilatation is generally present.

The importance of syphilis as an etiological factor in the production of pyloric stenosis has been variously estimated by different authorities. Engel reports a syphilitic history in 10 per cent of all his ulcer patients. Stockton has reported several in which the symptoms have yielded promptly to antisyphilitic treatment, and numerous autopsies have demonstrated beyond a doubt that gummata and typical syphilitic ulcers may exist at or near the pylorus and give rise to more or less serious obstruction.

Among the rare forms of pyloric obstruction may be mentioned foreign bodies, masses of hair, wool or other non-absorbable substances which have been swallowed and rolled into large balls by the muscular movements of the organ, also benign tumors of the liver, gall-bladder ducts or pancreas pressing on the stomach or duodenum, enlarged lymph nodes and possibly kinking of the duodenum from gastroptosis or movable kidney. Mayo has described a volvular formation due to inflammatory shortening of the gastrohepatic omentum.

In considering the clinical history of pyloric obstruction it must be borne in mind that we may and frequently do have two distinct groups of symptoms; first, those due to the disease which gives rise to the stenosis, and second, those due to pyloric narrowing and the resulting gastrectasia and the chemical changes which occur in the retained gastric contents. The first effect of pyloric narrowing is retardation in the normal emptying of the stomach after an ordinary meal. This may give rise to no subjective symptoms, and the only indication of such retardation may be that furnished by the use of the stomach tube which shows that the viscus still contains a portion of the ingested food at a period when it should be empty. Riegel states that after an ordinary meal, the stomach should be found empty in seven hours. In mild degrees of motor insufficiency, food will still be found in the stomach seven hours after a meal, but not in the early morning after a light supper the previous evening. In general the degree of motor insufficiency may be estimated by the amount of food residue found at various times after the taking of a test meal.

Occasionally patients with mild degrees of motor insufficiency complain of a sense of weight and discomfort in the epigastrium after a heavy meal but not when a moderate amount of food is taken. There is, as a rule, no actual pain and the symptoms disappear as soon as the stomach is empty. In more advanced cases of stenosis, where compensation is present, the peristaltic movements of the stomach can occasionally be seen or felt through the abdominal wall. This may be associated with a subjective symptom which Kussmaul has described as peristaltic unrest. When the stomach begins to dilate and fermentation takes place, the patients complain of a greater degree of fulness and epigastric pressure after each meal. Eructations occur, which may be odorless or foul, from the presence of sulphureted hydrogen. Not infrequently heartburn is present from the occurence of fatty acids in the fermenting gastric contents.

Of all the symptoms of pyloric obstruction, however, vomiting is the most important and characteristic. It may occasionally occur in the earlier stages of motor insufficiency before dilatation has taken place, but when gastrectasia and fermentation are developed it is more or less constantly present, and in the most advanced cases it occurs after each meal.

It is characterized by the large amount of food expelled at one time and the fact that the vomited matter often contains particles of food taken the day, or several days, before. As a rule the vomitus is acid in taste and smell, and often foul from decomposition. When allowed to stand it generally separates into three distinct layers—the upper of froth, the middle of a grayish fluid and the lower of solid particles of food.

As vomiting gives relief in the majority of instances, patients not infrequently get into the habit of inducing it whenever the gastric distress is severe. In advanced grades of pyloric obstruction, the patients suffer greatly from lack of fluids. This gives rise to intense thirst, dryness of the skin and mucous membranes and a marked diminution in the excretion of the urine. Crämer is accustomed to estimate the degree of dilatation by the quantity of urine excreted, dividing his patients into three classes, the mild when 1,500 c.c. or more is excreted in twenty-four hours, those of medium severity when the urinary excretion is reduced to 1,000 c.c. and the severe cases when the excretion is 500 c.c. or less.

Loss of weight necessarily begins as soon as the stenosis reaches such a degree that the requisite amount of food is not forced into the intestine, it is usually progressive and in the end emaciation is extreme. Progressive anemia is present in all of these cases, the degree generally corresponding with the rate of emaciation.

In the later stages of gastrectasia patients generally complain of loss of appetite, headache, mental torpor and various paresthesias. In a certain number of cases tetany will develop, evidenced by the occurrence of tetanic contractions in the hands, arms and legs, with occasional trismus and transitory blindness. This frequently follows severe vomiting or an attempt to pass a stomach tube, and unless gastric drainage is at once instituted, the disease proves fatal in a large proportion of the cases.

With the exception of those cases where a tumor can be planted in the pyloric region, there are no physical signs which help us to a diagnosis in the early stages of benign stenosis. When gastrectasia occurs, however, physical examination frequently furnishes important data. Inspection will often reveal the outlines of a dilated stomach through a thin abdominal wall. Occasionally the greater and lesser curvatures can be palpated, and splashing may often be elicited at a time when the stomach should normally be empty. Distending the stomach with air or water will often enable us by percussion to identify its limits and thereby form a fairly reliable estimate of its size. In general it may be stated that with the lesser curvature in its normal position, when the greater curvature can be demonstrated at or below the umbilicus, dilatation is presnt.

The foregoing description applies only to instances of uncomplicated benign pyloric stenosis. It is perhaps the exception to find adult cases which present such a typical clinical history, as

the symptom complex in the majority of instances is modified by the occurrence of some preceding or accompanying pathological condition which gave rise to the stenosis.

In those cases due to ulcer therefore we are apt to have a history of digestive disturbance long before the signs of pyloric obstruction occurred. In the majority of instances such patients complain of more or less acute attacks of epigastric pain after eating, often with vomiting of acid material at the height of the attack.

They have generally restricted their diet because certain articles of food seemed to produce more distress than others, and as a result are frequently emaciated and anemic. There may be a history of hematemesis or melana.

In those cases in which the stenosis is due to the late contraction of the scar of an ulcer, or to peritoneal adhesions due to ulcer, there may be a distinct interval between the symptoms of ulcer and those of pyloric obstruction. In the great majority of cases, however, the history would indicate that the early symptoms of obstruction were due to the induration surrounding an open ulcer, and in these instances the cardialgia, eructations, epigastric tenderness and vomiting overshadow for a time the comparatively mild symptoms of early motor insufficiency. Under these conditions the pain is often more severe than in ulcer without obstruction, due to the mechanical irritation of the ulcer by the increased muscular action of the stomach to force the food into the intestine. While the pain is frequently limited to a small area in the epigastrium which is often exquisitely tender, it may radiate to the back, the breasts, to the neck or hypochrondriac regions. The suffering in these cases is often extreme until relieved by vomiting of an abundant acid material.

Hyperchlorhydria is present in practically all of these cases, as demonstrated by gastric analysis. Not infrequently there is in addition a more or less continuous secretion of gastric juice evidenced by morning vomiting of a cloudy acid fluid containing a few flakes of solid matter. Later when dilatation has occurred this morning vomiting contains remnants of food taken the evening before.

As in other cases of gastric ulcer, the symptoms may undergo marked variations in intensity, owing to care exercised in the diet and the employment of rest and other remedial measures.

It may happen that the symptoms of ulcer may cease entirely, leaving only those of a progressive gastrectasia; on the other hand the pain may persist throughout the disease to the end. In the later stages of the affection, the appetite which in the beginning with an abundant hyperchlorhydria was exaggerated, almost invariably is lost and there is instead a disgust for food of any kind.

In those cases of obstruction due to adhesions from gall-bladder suppuration, there is usually a history of attacks of pain in the upper abdomen, which, however, do not exhibit the same relation to the taking of food as in gastric ulcer. In these attacks the pain and tenderness are located chiefly in the right hypochondriac region and the vomiting when it occurs is mostly at the beginning of the attack. There is no evidence of hyperchlorhydria. In addition there is generally a history of one or more severe attacks accompanied by fever and other evidences of local peritonitis. The occurrence of jaundice is occasionally mentioned.

As the symptoms of gall-bladder and duct disease are practically always intermittent, with long intervals of quiescence, the presence of pyloric obstruction and gastrectasia, is generally indicated by the occurrence of more or less typical symptoms of this condition which, however, may at any time be interrupted by those of an acute gall-stone colic or attack of cholecystitis.

Although it would be quite impossible in the limited time at my disposal to review the symptomatology of all of the rarer lesions giving rise to pyloric stenosis, I desire to call attention briefly to one of the varieties of this malady which has not received from the profession at large the attention it deserves.

Congenital stenosis of the pylorus was first described by Beardsley, of New Haven, in 1788. Meltzer, in the *Medical Record* of July 20, 1898, reviews the literature of the subject and gives the clinical history of a case under his care, together with the appearances found at operation and the pathological report of the specimen obtained at autopsy.

Dorning has recently reported another case with typical symptoms, in which he was able by palpation to detect a pyloric tumor during life. He stated that at the time of his report, about sixty cases had been recorded. Meltzer states that the life history of these cases may be divided into three phrases: First, the period of simple muscular insufficiency; second, an attempt at compensation, and third, the stage of atony and progressive dilatation.

The clinical histories of the reported cases show a striking similarity, and correspond to the three periods described by Meltzer.

At first the child nurses with avidity but soon regurgitates the meal. After several such attempts the mother generally finds that if a small feeding only is allowed it may be retained. Vomiting may therefore be infrequent for a few weeks after birth, the frequency depending largely on the degree of stenosis. During this period the child is generally restless between feedings and shows evidence of constant thrist. Sooner or later the stage of atony and dilatation occurs and the vomiting becomes more frequent and exhausting. The child grows progressively weaker, emaciates and may develop stupor and other nervous symptoms. At this period the stomach can generally be demonstrated to be dilated and flaccid, the urine is scanty and constipation is marked.

The use of the stomach tube is of great value in confirming the diagnosis in these cases. The presence of food in the stomach two hours after a feeding, when associated with the above symptoms, is sufficient to establish the diagnosis.

In considering the treatment of benign pyloric stenosis it seems hardly necessary to say more than a few words to an audience the members of which appreciate so keenly the fact that the cause of all the untoward symptoms of this disease is purely a mechanical one, and can be relieved only by reestablishing a normal connection between the stomach and intestine. It would be a waste of time even to consider drugs, massage, electricity and lavage, which at best can only be regarded as palliative measures. With the exception of the few instances in which the obstruction is so light that the symptoms can be easily relieved by dietetic regulation, or in those exceedingly rare cases where the stenosis is due to a syphilitic ulcer or gummatous deposit, and which quickly respond to anti-syphilitic treatment, surgery and surgery alone can offer relief to these patients. In perhaps no other class of operations upon the alimentary canal have the results of surgical intervention been more strikingly satisfactory.

It will sometimes be possible to remove the causes of the stenosis by operation, such as peritoneal bands or adhesions, new growths or enlarged lymph nodes pressing upon the pylorus or first part of the duodenum, foreign bodies or benign tumors of the stomach wall. In the majority of instances, however, it will be necessary either to enlarge the contracted pyloric orifice by plastic operation or to create a new opening between the stomach and small intestine. Digital dilatation of the pylorus has been abandoned by surgeons.

The original pyloroplasty of Heinecke-Mikulicz is gradually giving way to other more radical procedures for the reason that recurrences after its employment were frequent. The operation of Finney and posterior gastro-enterostomy are the two procedures employed at present for the relief of pyloric stenosis. Finney's operation which consists in enlarging the pyloric opening by a plastic operation which unites the first portion of the duodenum with the adjacent wall of the stomach is the operation of choice in cicatricial stenosis where the tissues are not too much infiltrated, in all other cases gastro-enterostomy is to be preferred. The technic of these procedures is so well known that a description of it here would be superfluous.

As the mortality of these operations are capable in hands, where the physical condition of the patient is still fairly good, should be below 6 per cent. in benign cases, and as a permanent cure may be expected in the majority of cases, it is difficult to appreciate why the rank and file of the profession should not give their unqualified approval to this method of treatment and why it is not more generally practised.

CASE OF PEPTIC ULCERS AFTER GASTRO-ENTEROSTOMY CAUSING GASTRO-COLIC AND JEJUNO-COLIC FISTULAE, AND OF SPONTANEOUS CLOSURE OF GASTRO-ENTERO-ANASTOMOSIS.[1]

BY J. KAUFMANN, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE GERMAN HOSPITAL.

THE history of the case which I want to report to you presents a remarkable development of gastric disturbances following a gastro-enterostomy, performed in December, 1901, on a man then forty-four years of age.

During the three years previous to this operation, the patient had suffered periodically from more or less severe gastric pains. Three times severe hematemesis had occurred and once there were all the symptoms of perforation, followed by localized peritonitis in the pyloric region. There was hyperacidity, some motor insufficiency and a pyloric tumor, which during the time of pronounced disturbances could easily be felt as a hard mass and which as a rule became smaller and less distinct after treatment.

Three times a strict treatment for ulcer had been carried out and in addition to this at several periods local treatment, lavage with silver nitrate, bismuth, etc., had been used. Once a long course of specific treatment was given because one of the patient's former physicians had diagnosed syphilis on account of an eruption on the lips and hands which he had treated several years previous to the development of the gastric symptoms and which had yielded only to iodide of potassium. The patient and his former physician denied syphilis most emphatically. However, since there was a difference in the size of the pupils both of which reacted poorly to light, the mercurial treatment was given a trial with no perceptible effect upon the ulcer. Nine months after the specific treatment, the third and most profuse hematemesis took place.

After renewed internal treatment for ulcer following this hematemesis had been rigidly carried out for six weeks, the patient vomited great quantities of strongly acid, fermenting masses, mixed with blood, and showed visible gastric peristalsis. These symptoms of increasing pyloric stenosis and the recurrence of hematemesis in spite of all the internal treatment, led to the operation.

At the operation, performed in December, 1901, by Dr. Lange, the pylorus was found to be thickened and its posterior wall adherent. Its anterior surface showed areas of marked thickening and opacity of the serous covering, one spot, probably the seat of the former perforation, being distinctly retracted. Retrocolic posterior gastro-enterostomy was performed. A very high jejunum loop had been taken and since the angle caused by the fixation seemed rather acute, the

[1] Read at the Eighth Annual Meeting of the American Gastro-Enterological Association, New York April 24 and 25, 1905.

afferent and efferent portions of the jejunum were connected by an entero-anastomosis. Silk sutures were used. Recovery was smooth, the only disturbance being caused by pronounced constipation during the first week. During the following three months there were no gastric symptoms and the patient gained 27 pounds. After this time gastric disturbances recurred. At first these were of mild character; pressure and discomfort about an hour after meals, but were followed later on (May, 1902) by more severe abdominal pains regularly coming on in the afternoon. On examination, the pyloric resistance was distinctly palpable, the stomach appeared large and atonic, and the stomach contents showed pronounced hyperacidity.

In October, 1902, severe cerebral symptoms appeared: difficulty in speaking and writing, defective memory, muscle tremor, exaggerated reflexes, papillitis on both sides, convulsions and periods of unconsciousness with complete amnesia afterward. Energetic mercury treatment was given and large doses of iodide of potassium for a long period. In February and March a few shorter attacks of mental disturbance occurred. After this there were no more cerebral symptoms.

In April, 1903, the abdominal pain which had hitherto been of a moderate character, became very severe. It generally came on in the afternoon or at night and was of such severe character that nothing but morphine would relieve it.

As a rule this pain was located in the upper abdomen, but at times it irradiated into the lower. While it lasted, the transverse colon could often be felt as a stiff, sausage-like tumor, which became softer when the pain grew less. This feature was especially noticeable after the administration of morphine. One could often feel gas escape with the relaxation of the tumor.

For periods of weeks and months the pain came on almost daily. There were other periods of weeks and even of months of perfect freedom from abdominal pain, especially in the summer of 1903 and 1904, while the patient was in the mountains. In November, 1903, six months after the abdominal pain first became severe, the patient complained for the first time of sulphurous taste and belching for several days and then vomited large quantities of fluid fecal matter. Lavage of the stomach was begun. The vomiting was not repeated but the complaint of fecal taste and the finding of fecal matter in the stomach became more and more frequent and finally, during the winter of 1904-1905, became constant. At first there were periods of weeks and months when stomach lavage performed at any hour of the day showed absolutely no fecal matter. During such periods, which were noted as late as the summer of 1904, examination of the fasting stomach and after test-meals showed pronounced hyperacidity and good motor activity, or at most, motor insufficiency of a mild degree. Even at the periods when fecal matter was found in the stomach, there were no signs of stagnation of food taken by mouth.

At the periods when fecal matter got into the stomach, it was often found in the fasting organ. Very often it entered the stomach only after a meal. The patient could recognize it by the fecal belching and could verify it by removing fecal matter from his stomach by the tube, even when the stomach had been cleaned by lavage before the meal. The same phenomenon was observed during lavage. After the wash-water had returned from the stomach perfectly clear several times, it would suddenly become mixed with fecal matter. Sometimes the flow of fecal matter would continue as long as the washing was kept up. The quantities of fecal matter thus removed by the tube were often very large.

Occasionally small formed feces were found. As a rule, however, the fecal masses were more fluid; they were in every way like the fecal matter obtained by defecation, in color and smell, in macroscopic and microscopic appearance. When removed from the stomach in the morning or a number of hours after meals, they never showed undigested food remnants.

The feces obtained from the rectum were large, semisolid, mostly light-gray, often acid from gas fermentation, showed enormous quantities of bacteria and were always well digested. Undigested food remains were never found, even when the stools were washed through a sieve. The chemical examination showed neither hydrochloric acid nor pepsin; albumin digestion examined by Mette's method, proved negative. Defecation was on the whole regular but at times, especially during attacks of severe pains, constipated.

There was no stagnation in the stomach of food taken by mouth; fecal matter would enter the stomach, but we could not demonstrate that stomach contents entered the colon. The existence of a gastro-colic fistula was finally proved by the following test:

A prolonged lavage of the stomach with consequent removal of great quantities of fecal matter was directly followed by a prolonged lavage of the rectum and colon. When the wash-water from the colon appeared somewhat clear, a suspension of lycopodium stained by gentian violet was introduced into the colon under slight pressure. A second lavage of the stomach carried out immediately afterward again produced great quantities of fecal matter, which on microscopical examination proved to be thoroughly mixed with the stained lycopodium.

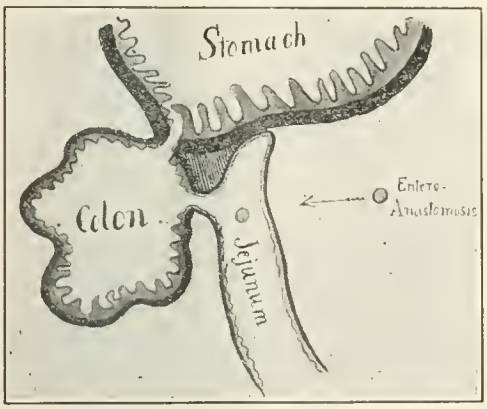
During the winter of 1904-1905 the condition became unbearable. The severe abdominal pain occurring at all hours of the day and at night made the patient a confirmed morphinist. Three more courses of specific treatment (April, 1903, June, 1903, January, 1905), had no effect; nor did any other treatment give relief.

The patient, being very much annoyed by the

constant flow of fecal matter into the stomach readily consented to the proposed operation.

The operation performed by Dr. Gerster (March 7, 1905), showed the middle portion of the transverse colon to be somewhat stiff and narrowed. It was adherent above to the larger curvature of the stomach, and posteriorly to that loop of the jejunum which had been used in performing the gastro-enterostomy. The apex of this greatly dilated loop was hidden behind the colon. After turning up the colon, we found a connection between the posterior wall of the

Fig. 1.*



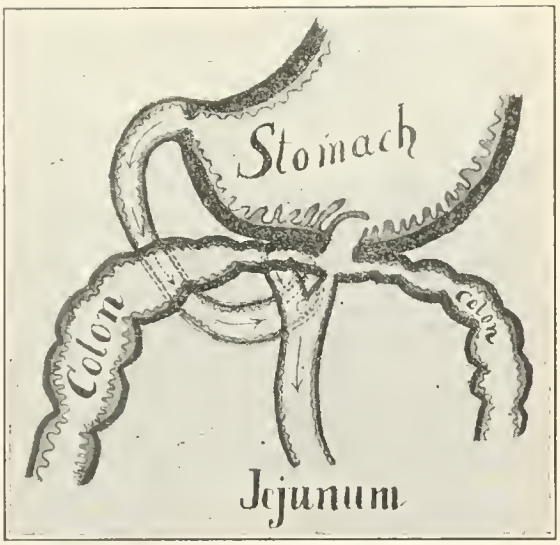
colon and a diverticulum of the jejunum, which must have been formed by traction. On section, this connection proved to be an open channel of considerable diameter between the cavities of the colon and the jejunum. The edges of the openings were soft and covered by mucous membrane. They showed neither infiltration nor ulceration. Both openings were closed by a Lembert suture. Then the colon was reflected and after the removal of a number of omental adhesions, it became evident that there existed another and larger connection between the upper surface of the transverse colon and the posterior wall of the stomach, which on dissection was also found to be an open channel uniting the cavities of the stomach and the colon. These two apertures, the edges of which were also soft and covered by mucous membrane, were sutured. It then became evident that the two openings connecting the colon, on one side with the stomach and on the other with the jejunum, were quite near together. The colon, which was already somewhat narrowed, became still narrower in consequence of this double suturing, to such an extent as to cause fear of a pronounced stenosis.

We had the choice of resecting this narrowed portion of the colon or of connecting the ascending colon with the sigmoid flexure. The latter proceeding was adopted because the intimate and extensive adhesions of the colon to the posterior parieties made resection a very hazardous undertaking. Since the operation had already lasted three hours, the Murphy button was used.

Recovery seemed uninterrupted during the first six days after the operation. Suddenly, on the sixth day, symptoms of perforation developed, followed by collapse. Immediate laparotomy showed that the perforation was caused by a continued necrosis of the sigmoid flexure, issuing from the site of the Murphy button.

I quote a few points from the post mortem: "On studying the relation of the fistulæ after removing the sutures, we found: (1) A hole in the stomach, surrounded by enormously hypertrophic folds of the gastric mucous membrane, one of which covered the hole from the gastric side completely and acted as a valve. (2) That the two holes in the colon were quite close to each other. In cutting the sutures the intervening bridge was destroyed. The upper hole corresponded to the hole in the stomach, and the lower one to the opening in the jejunum. The gastro-colic and the jejuno-colic fistulæ were opposite each other, so that a glass probe could be passed directly from the stomach through the two holes in the colon into the jejunum; (3) That the hole in the jejunum was situated in the diverticulum of the efferent portion, which was very much dilated; the afferent portion was short and formed a straight line from the plica duodeno-jejunalis toward the stomach.

Fig. 2.*



Absolutely no traces could be found of the opening between the jejunum loop and the stomach, which was made at the primary gastro-enterostomy. The apex of the jejunum loop was adherent to the lower surface of the transverse mesocolon, but it was entirely separated from the stomach. The opening of the entero-enterostomy, though small, was still patent: it was in close vicinity to the jejuno-colic fistula, which was about 5 cm. below the apex of the jejunum loop. The pylorus was patent, but at

* The drawings do not give the exact anatomical relations and are meant to be only diagrammatic. The jejunum-loop is here shown attached to the stomach, in order to demonstrate the situation of the former gastro-entero-anastomosis.

one point markedly narrowed, showing on its inner surface the scar of the old ulcer.

The transverse colon at the level of the fistulæ was thickened and measured only 7 cm. in circumference, while the hepatic part of the transverse colon was dilated to 10 cm. circumference and thinned out. The descending colon measured only 4¼ cm.

There were no anatomical evidences of syphilis, either in the vessels or the viscera (including the brain and the testicles). The larger branches of the abdominal aorta showed slight arteriosclerotic changes. The smaller ones and the thoracic aorta and its branches were free.

In reviewing this case, we must consider separately: (1) The closing of the gastro-entero-anastomosis. (2) The formation of the fistulæ.

The gastro-entero-anastomosis had entirely disappeared. The closing of the anastomotic opening was so complete that it was impossible to locate it. Even the connection between the jejunum-loop and the stomach did not exist any more; the jejunum loop was entirely separated from the stomach. We cannot say how soon after the operation the anastomosis had closed up. So far only a few anatomical facts have been reported, which give information about the final outcome of gastro-entero-anastomosis in benign cases.

G. Gayet described a case which showed the same conditions as our case. He found at a second operation performed one year after gastro-enterostomy, that the first opening had completely closed, that the intestine had been absolutely separated from the stomach, and was only kept adherent to the transverse mesacolon.

Mayo, Feldmann, Robson and Moynihan have reported cases in which a second operation was performed, because the anastomosis had closed. In most of these cases it is simply stated that the opening had contracted; in only one case is it specifically stated by Robson and Moynihan, that the opening had completely closed. There are further a few reports of findings at postmortems: Ferrari found in one case, three years after operation, an anastomosis of only 2 mm. diameter; in another case, six months after operation, an opening of 4 mm. diameter. Jaboulay reports an autopsy after six months, another after a year, with the opening very much restricted. In another group of cases, the opening was found still patent; in Cordier's, even six years after the operation. I saw the opening patent in a case (not published); two years after the operation. More facts must be obtained before we can explain why the anastomosis remains open in one case and closes in another. The complete disappearance of all traces of the anastomosis in our case is certainly very remarkable.

In regard to the development of the fistulæ I would like to suggest the following explanation: The abdominal pains from which our patient suffered so severely must be attributed to a new gastric ulcer which developed near the former gastro-entero-anastomosis. We may class this ulcer with the group of peptic ulcers following gastro-enterostomy. Tiegel has recently published a review of 22 such cases, in which the peptic ulcer was demonstrated either at the post mortem or at a second or third operation. In most of them the peptic ulcer was found in the jejunum. In some it developed directly on the edges of the gastro-entero-anastomosis. In one case, reported from Czerny's Klinik, a peptic ulcer had developed in the stomach near the gastro-entero-anastomosis, caused adhesions to the colon, and had then perforated into the colon, thus forming a gastro-colic fistula.

The same process, in all probability, took place in our case, but in addition, after the gastro-colic fistula had developed, a second peptic ulcer formed in the colon, opposite the fistula. This second ulcer in turn led to adhesions to the jejunum, into which it perforated, thus forming the jejuno-colic fistula. As a result of these ulcerative and perforating processes adhesions were formed between the stomach and colon, and the colon and jejunum leading to a narrowing of the involved part of the transverse colon.

During life this section of the colon could often be felt as a sausage-like tumor, stiffened by spastic contractions. The spasms were probably caused by the irritating effect of the highly acid gastric secretion on the colon, in the same way in which pylorospasm is caused in case of pyloric ulcer. The frequent spastic contractions of the colon may have contributed to another effect of the adhesive processes, *i.e.*, the formation of the diverticulum of the jejunum by traction.

The fact that we did not find undigested food in the feces is fully explained by the presence of the large fold of the gastric mucosa which, acting as a valve, easily prevented the passage of formed masses from the stomach into the colon, although it could not prevent the flow of gastric secretion into the colon.

The manner in which these peptic ulcers develop after gastro-entereostomy is not yet clear. According to Tiegel, it does not seem that the technic of special methods has great influence, since a study of his 22 cases shows that they occur after all the different methods of operating. Since they occur only in cases of benign diseases of the stomach, it is probable that on the whole the conditions for the development of such peptic ulcers are the same as those for the development of the primary ulcer, *i.e.*, chronic gastritis, hyperacidity, circulatory disturbances, etc. The locality, however, in which the peptic ulcer appears, makes it certain that the operation itself is the direct cause of its development. Perhaps lesions of the mucous membrane, created at the operation, form the basis for the peptic ulcer. Tiegel names arteriosclerosis as a contributory cause. It hardly touches the question in our case, since the arteriosclerotic changes were only moderate and con-

fined to the larger branches of the abdominal vessels.

We have further to consider the question of syphilis in our case. Even if we assume that the patient at one time had syphilis, there is nothing that would permit us to connect it with the formation of the gastric ulcers and the fistulæ. A thorough anatomical examination of the abdominal viscera showed no signs of syphilitic processes, nor did the repeated and prolonged anti-syphilitic treatment yield any apparent result.

At present, syphilis is frequently accused of causing gastric ulcer. However, in only a comparatively small number of cases, has this connection been proved by anatomical examination (Flexner-Trinkler). The mere fact that a patient with gastric ulcer suffers or has previously suffered from syphilis cannot be taken as sufficient proof. In our case the thought of syphilis was for a long time misleading in the interpretation of the predominant symptoms. The attacks of severe abdominal pain, which occurred after the development of cerebral symptoms, we at first regarded as gastric or enteric crises caused by syphilitic disturbances of the cerebro-spinal system. Even when fecal matter was found in the stomach, it was considered doubtful whether we had to deal with organic or only functional disturbances, because the fecal matter was found only during certain periods, while at other periods of weeks and months the stomach was free, and also because the patient showed other symptoms of hysteria. The lycopodium test settled this question definitely, proving the presence of a gastro-colic fistula.

It is probable that a knowledge of the frequency of peptic ulcer after gastro-enterostomy would have made clear the true nature of the disturbances in our case before the post mortem.

The development of peptic ulcer after gastro-enterostomy is by no means rare. The 22 cases collected by Tiegel are only cases in which the peptic ulcer was demonstrated at a second or third operation, or at the post mortem. Eight of these 22 cases had shown absolutely no symptoms until suddenly perforation occurred. We may, therefore, conclude that in all probability a great number of cases escape detection.

We ought to bear in mind the possibility of peptic ulcer, whenever gastric disturbances recur after gastro-enterostomy. In fact, we should keep it in mind whenever gastro-enterostomy has been performed and regulate accordingly the treatment after the operation. The great immediate relief after such operations and the apparent immunity with which ordinary meals are digested, too often leads the surgeon to allow a liberal diet. It should be remembered that the chronic gastritis and the hyperacidity which accompany the primary ulcer, do not disappear immediately after operation, and that if not treated properly they may contribute to the development of new ulcers. The further surgical treatment of peptic ulcer following gastro-enterostomy has given very poor results. Complete recovery is rare; fatal issues frequent.

A careful consideration of all these facts should tend to restrict the indication for gastro-enterostomy, which otherwise gives such excellent results in certain benign gastric diseases.

SOME OBSERVATIONS ON THE RELATIONS OF THE GASTRO-INTESTINAL TRACT TO NERVOUS AND MENTAL DISEASES.[1]

BY ROBERT COLEMAN KEMP, M.D.,

OF NEW YORK;

CONSULTING PHYSICIAN, GASTRO-INTESTINAL DISEASES, TO THE MANHATTAN STATE HOSPITAL, WEST, WARD'S ISLAND, ETC.

As I have not the honor of being a member of the American Medico-Psychological Association, or even a neurologist, I assure you that I appreciate all the more the invitation of your secretary, my friend, Dr. Dent, to read a paper before you. I have selected as my title, "Some Observations on the Relations of the Gastro-Intestinal Tract to Nervous and Mental Diseases." You are all doubtless familiar with the investigations of Bouchard, Vaughan, Novy and Herter and many others, on the subject "auto-intoxication," and it must be evident to you that my remarks will be entirely based upon this theory. This field opens up enormous possibilities, and although much good work has already been carried on, I believe the subject to be really in its infancy. For your complete understanding, it would seem to me to be advisable first to refer to the physiology of digestion.

There are certain inorganic ferments contained in the bile, saliva, gastric juice, pancreatic juice and intestinal juice, which are a part of the human organism at birth. There are furthermore many organic ferments which are immediately acquired after birth, and which play an important part both in the physiology and in the pathology of the gastro-intestinal tract. At birth, this tract is sterile, as is confirmed by examination of the meconium. It is first infected in the new-born infant by the swallowing of air, and then with the bacteria of the food and the saliva. The feces of the adult and nursling contain bacteria to the extent of approximately one-fourth to one-third of the dried weight of the excretion—which would sum total many millions. With normal digestion, fermentation of the carbohydrates in the small intestines is produced by the micro-

1 Read at the Sixty-first Annual Meeting of the American Medico-Psychological Association, at San Antonio, Texas, April 21, 1905.

organisms therein to a physiological degree, the organic acids, lactic and acetic, the derivatives of such fermentation, acting as a stimulus to normal peristalsis. These acids prevent the putrefaction of albuminates within the small intestines, and partly check the decomposition of the carbohydrates. The putrefaction of the albuminates physiologically takes place in the large intestine, the contents have an alkaline reaction. Here are developed skatol, which gives the odor to the feces, indol, phenol and various gases, and the other products of putrefaction. The *Bacillus coli communis* is believed to be an important factor in these putrefactive processes, and the production of indol depends largely on the activity. It is not a product of pancreatic fermentation as was formerly supposed. In this viscus also, a small proportion of fat is decomposed into glycerin and fatty acids, by the bacteria. When carbohydrates are present, as well as proteids, the colon bacilli ferment the carbohydrates first, and no indol is manufactured until this is nearly completed. Undoubtedly, putrefactive bacteria of various types are at all times present in the stomach and small intestines, but their activity is inhibited, until conditions favorable to their development arise. Thus normal fermentation of carbohydrates in the small intestine has this effect.

The first inorganic ferment which we find, is in the saliva, and this acts for the transformation of the carbohydrates. We must remember that proper mastication of the food, and care of the teeth, all have an important bearing on digestion. Acid fermentation in the mouth interferes with the action of the saliva, and, moreover, it has been demonstrated, that cleansing the mouths of nursing infants will, alone, diminish fermentative processes in the gastro-intestinal tract.

In the stomach we have the combined action of hydrochloric acid and the ferment pepsin on the proteids; the rennet ferment curdles milk and unless excessive hyperacidity be present, further fermentation changes occur in the sugars. Besides this, a small percentage of the fats is split into fatty acids. Meltzer has demonstrated that only a small quantity of water is absorbed from the stomach. Excessive hydrochloric acid, moreover, checks further changes in the sugars.

The motor functions of the stomach and intestines are of great importance. A small meal, such as a soft-boiled egg, a slice of toast and a glass of water, will pass through the stomach in about two hours; and at the end of this time, under normal conditions, only a small amount of gastric juice can be aspirated. About the same period of time, two hours, is consumed in the passage through the small intestines, and for about twenty hours, the final products remain in the large intestine before expulsion from the anus.

Normal peristaltic action of the stomach and intestines are, therefore, most important factors in the prevention of abnormal fermentation or putrefaction.

With atony of the stomach we have as a result motor insufficiency and stasis. It has been demonstrated that the presence of free hydrochloric acid, even in considerable quantities, does not prevent gaseous fermentation or putrefaction, if stasis be present. Simple atony of the stomach will often progress to chronic dilatation, and, in fact, I believe it to be a frequent course, if left untreated. With this dilatation, there may be increased fermentation or putrefaction. Butyric acid may be produced. This acid has a distinctly depressive effect on the central nervous system. Together with lactic and acetic acids, its presence indicates gastric stagnation, destruction of glandular elements by malignant or other disease, putrefaction or fermentation. Butyric acid is classified among substances acting as autotoxins. Hydrogen sulphide (H_2S) at times is found in dilated stomachs, together with other gases, the absorption of which cause toxemic symptoms.

In a recent work by Dr. Wm. H. Thomson, entitled "Graves' Disease, With and Without Exophthalmic Goiter," the author holds that gastro-intestinal toxemia is the cause of this disease, and describes some twenty-eight symptoms occurring in cases both with and without goiter. Curiously enough, ethylidenediamin, a ptomain found at times by Kulneff, in the liquids of the stomach, in dilatation of that organ, when injected into mice and guinea-pigs, will produce exophthalmos and some symptoms found in Graves' disease. This is of interest, and certainly suggestive. Mold in the stomach, hypoacidity, anacidity, chronic gastritis and achylia gastrica, may be found in dilatation of the stomach. It can thus be readily understood, how perversions of the gastric digestion may be a marked causative factor in the production of additional disturbances in the intestinal tract below, and be productive of excessive fermentation, or of putrefaction. A careful examination of the secretions and motor functions of the stomach is, therefore, one of the first requisites for scientific research into auto-infection from the gastro-intestinal tract.

Under normal conditions, when the chyme enters the small intestine, its reaction is acid, due to the hydrochloric acid contained therein. The bile is one of the chief factors in gradually altering this reaction to neutral or alkaline. It strongly supplements the action of the pancreatic juice in emulsifying fats and its absence, or diminution lessens this function. It, furthermore, precipitates the pepsin from the chyme, and allows it to be the more readily absorbed. Some consider that it has antifermentative and antiputrefactive powers, and that it helps maintain the nutrition of the epithelial cells. The bile exercises a distinct effect on the peristalsis of the intestines and certain noxious products are by it eliminated from the body.

The pancreatic juice contains an amylolytic ferment, a lipolytic ferment and a proteolytic fer-

ment, with which all are familiar. They act in a neutral or alkaline medium, though small quantities of acetic or lactic acid seem to favor their activity. The organic ferments, existing in the small intestine, aid in the production of these acids. According to Ewald, prolonged action of the pancreatic juice may produce hypoxanthin, but more probably it is due to excessive putrefaction. (Methyl guanidin results from the oxidation of creatin and creatinin and it illustrates how a comparatively non-poisonous substance may be changed into a violent poison by bacterial action. On injection of this substance into guinea-pigs there appear fibrillary twitchings, rapid respiration, dilatation of the pupil, dyspnea, labored breathing and clonic convulsions. All these phenomena are suggestive of epileptiform attacks. Creatin is found in muscle; creatinin, a derivative, is also derived from meat taken as food and appears normally in the urine. It is increased by meat diet, in diabetes, various fevers, such as typhoid, etc., and is diminished by anemia, etc.) Methyl guanidin results therefore from putrefactive processes in the small intestine and probably from the large intestine as well. This is a leucomain, which causes increased nervous irritability and tetanic convulsions, a fact of interest. During the process of normal amylolytic fermentation, organic acids are given off which are an aid to stimulating intestinal peristalsis, and these acids are of service in checking putrefaction. Peristalsis of the intestine also renders putrefactive changes less likely. Stasis of the intestine is an aid to putrefaction, just as is motor insufficiency in the stomach. Butyric acid and hydrogen sulphide are autotoxins, which may also be produced in the small intestines. The intestinal juice is claimed to augment the activity of the pancreatic ferments, according to Pawlow, and to help neutralize some of the acids formed by the fermentation of the carbohydrates. The reaction in the lower jejunum and ileum is acid. When the intestinal contents pass into the colon, the reaction becomes alkaline, fermentation stops, and putrefaction begins, and the fecal odor appears. In the large intestine great absorption of water occurs, the albuminates are taken up, as are also sugars and fats to a degree.

Marked auto-infection can occur from this viscus. Among the ptomains found after prolonged stasis are cadaverin and putrescin, which give the symptoms of muscarin poisoning. Moreover, indol, of which tyrosin is the chief source, is here developed. Herter has administered it to animals and observed cardiac and respiratory depression, marked contraction of the pupils, clonic spasms, and increased reflex irritability. Small quantities taken daily, for several weeks, produced nutritive changes, frontal and occipital headaches, colic, diarrhea, unnatural mental activity, and a tendency to the neurasthenic state. Indol is absorbed from the intestines, and forms indoxyl-potassium sulphate, or indican, and is so eliminated in the urine. The causes of indicanuria are excessive proteid diet, catarrh of the small intestines, causing alterations in the mucosa and increased intestinal putrefaction therefrom, typhoid, cholera, etc., constipation, alimentary putrefaction, decrease of normal digestive fluids, intestinal obstruction and peritonitis. Certain drugs, such as salol, salophen and creosote will cause its appearance, whereas urotropin will diminish it.

Regarding the urinary test for this condition, Jaffe's is the one frequently employed. Rosenbach's test, which consists in boiling the urine with nitric acid, gives a Burgundy-red. This also demonstrates putrefactive changes, but not invariably that indican is one of the elements. This sometimes occurs when no indican is found by Jaffe's test. The result is due to substances of a like class. Other conditions of the urine occur as a result of these toxemias from the gastro-intestinal tract, the appearance of albumin and casts, or diminished urea excretion. The kidneys may become damaged from these toxins, and in turn, toxemia from the kidneys may result. We must remember that absence of indican in the urine does not invariably indicate absence of putrefaction, as in diarrhea, the indol may be to a great extent eliminated. In some cases even when constipated, there are no evidences of indican, even when there are clinical signs of abnormal putrefaction. This demonstrates that there are other putrefactive substances besides indol. Finally the functions of the liver and its relations to toxemia must be briefly considered. We have already described the action of the bile in the intestines. The liver acts as a store-room of the organism, for peptones, and sugars in the form of glycogen, these substances being kept there until their final use in the system. It excludes poisonous matters from the general circulation by removing them from the portal vein and excreting them by the bile. Thus, Herter demonstrates that the liver is the chief organ for the removal of indol. Various poisons and other toxins, as of typhoid, etc., are similarly destroyed, or chemically changed. Therefore, any diminution of the functional mass of the liver, or interference with its functions, impairs this property and toxemia results.

The bile itself, when absorbed into the system, acts as a poison, and produces a definite toxemia. Moreover, catarrhal conditions of the intestines will often cause obstructive jaundice; or the colon bacillus may become a source of infection of the ducts and gall-bladder. Insufficiency of the biliary secretion, or the absence of bile from the intestinal tract, favors in turn those conditions which result in auto-intoxication—due to the induced obstinate constipation, from the absence of its antiseptic and peristaltic stimulant effect, and we have the well-known symptoms of bilious indigestion. You are all familiar with the slow pulse, and other symptoms of jaundice, unquestionably due to auto-intoxication.

Cholin, under normal conditions, is found in

the bile as well as in the blood and brain and, in intestinal disorders its amount is increased and it may appear in the urine. In dilute watery solutions it may be transformed into neurin which is still more toxic. Large doses of cholin cause nearly instantaneous death in cats and rabbits. In experimental poisoning, there are dilatation of the peripheral blood-vessels, lowering of the blood pressure, salivation, spastic contractions and stoppage of the heart in diastole. It is an important factor in auto-intoxication on account of its relation to nervous disorders. Nerin, a derivative of cholin, on injection into animals, causes dyspnea, salivation, mydriasis, irregular and labored respiration, unconsciousness and clonic convulsions. Muscarin is believed to be often associated with cholin and it also causes convulsive seizures. It is also found in mushrooms and in decomposing fish. All these substances produce epileptiform seizures.

It is interesting to note that hepatic disease may be produced experimentally by substances allied to the autotoxins, thus in the production of hemoglobinemia by the injection of free hemoglobin, or of distilled water, jaundice is produced. Furthermore, poisons circulating in the blood cause a change in normal bile, in which it increases in viscidity, causing agglutination of the walls of the bile ducts, obstruction of their lumen, and consequent retention of bile within the sac. Stadelmann was able to produce a jaundice experimentally in animals by poisoning them with arsenureted hydrogen and toluenediamin, and found that there was an enormous increase in the biliary secretion, and that it was very thick and tenacious. Autopsies showed no catarrh of the duodenum, nor obstruction of the common duct. Moreover, the bile acids, if injected, cause disintegration of the red blood corpuscles, with liberation of hemoglobin. They delay the coagulation period of the blood, and reduce motor and sensory irritability, and may cause coma, insensibility and death.

It is evident, therefore, that the liver cannot produce normal bile from abnormal blood; and the fact that jaundice is caused by exposure to cold, syphilis, typhoid, phosphorus and other poisons, shows how easily the secretion of the bile is altered, and suggests that intrinsic poisons, which are often hemolytic in their action, may act a causes. Toxic materials absorbed from the intestinal tract, or from the urinary tract, in addition, may cause altered secretions, and the retention of bile from its own viscosity may ensue. The absorption of bile is, therefore, a serious complication, when surgical operations are necessary, owing to the increased danger of hemorrhage on account of the lengthened coagulation period. In fact, hemorrhages from the various organs at times ensue, even subcutaneous in character; a condition like purpura hemorrhagica. For this condition, large and frequent doses of calcium chloride have been recommended. Moreover, the toxemic condition causes these patients to take anesthetics badly, and renders them liable to shock and collapse, and they have little resistant powers against sepsis and disease.

Having thus described the relations of the gastro-intestinal functions to toxemia, at this point I wish to call to your attention several important propositions: (1) that epileptiform seizures, or even true epilepsy, may in some cases result from auto-infection; (2) that in many cases of nervous or mental diseases, derangements of the gastro-intestinal functions with resulting auto-infection may aggravate the original condition from which the patient may be a sufferer, and thus create a vicious circle; (3) that it is our duty as physicians, as much to our poor asylum, as to our private patients, to place them in the best possible physical condition.

And, finally, that on the patient's admission to such institution, a thorough investigation should be made in each individual case, into the existing conditions of the gastro-intestinal tract, and appropriate treatment be instituted in each; for by this means alone, can a scientific study of the relations of toxemia to nervous and mental diseases and the results of treatment be obtained. My friend, Dr. Dent, is the first one to appreciate the value of this method; and, as I shall describe to you later, it has already been instituted at the Manhattan State Hospital, West, Ward's Island.

I shall first consider epileptiform convulsions and epilepsy, resulting from toxemia from the gastro-intestinal tract. I judge that you are all familiar with the fact that the carnivora are susceptible to convulsive seizures from dietetic disturbances, whereas the herbivora are exempt. It is, furthermore, interesting to note, that the administration of meat to young dogs will often be productive of convulsions. The intestinal walls of infants permit the passage of proteids, whereas those of adults do not, which may account for the greater frequency of nervous manifestations in children. Moreover, red meats in every event tend to aggravate nervous conditions, and it is customary, in the modern treatment of epilepsy and in many nervous diseases largely to eliminate them from the dietary. I have, furthermore, noted in my own cases of epilepsy resulting from toxemia, that the patients were large eaters, especially of the red meats.

Some thirty years ago Meynert attributed epilepsy to the accumulation of a toxic substance of a proteid nature. The convulsive element is very prominent among the various autotoxins developed in the intestinal canal, notably with hypoxanthin poisoning, with methyl guanidin and with neurin, the symptoms of which we have already described. The studies of Ceni on epilepsy also demonstrate that it is of autogenous origin and the fact that no immunity occurs from repeated attacks and that the serum which he devised has no inoculatory power shows that the process is not bacterial in its nature. It would seem, as will now be demonstrated, that certain cases at least must have as their source, auto-

infection from the gastro-intestinal tract. I shall first consider epileptiform seizures in the young.

In our study of convulsive seizures in infants and young children, resulting from the administration of improper food, or from overloading the stomach, it was possible to distinguish two classes of cases—gastric and enteric. In the gastric cases, the convulsive seizures come on a short time after the administration of food, half an hour to an hour, or even less, and emesis often produces immediate relief. I have noted acute dilatation (distention) of the stomach in these patients. Just as in adult cases, to which I shall shortly refer, I believe, this acute dilatation, to be caused by auto-infection, resulting from fermentative or putrefactive processes in the stomach. Such attacks, continuously repeated, may predispose to the convulsive habit, and become a factor in the production of epilepsy. Furthermore, repeated attacks may tend to render the stomach atonic, and may result in chronic dilatation, with chronic toxemia as a result. I have referred to this class of cases in my article, entitled "Observations on Dilatation of the Stomach on Gastroptosis," MEDICAL NEWS, August 6, 1904. In the enteric type, the convulsions occur several hours after the administration of food, and are relieved by the use of an enema. These result from toxemia from the intestinal canal. Castor oil or calomel should then be used as adjuvants.

We may have, instead of these well-defined types, a combination of the two. Holt and many others believe that intestinal putrefaction, exciting convulsions in young children, is an important factor in the production of epilepsy. Repeated convulsions certainly predispose to the convulsive habit. On the other hand, chronic dilatation of the stomach in the young, may result from improper feeding and the products resulting may be a cause of toxemia from the stomach direct, or after entrance into the intestines. A condition of chronic toxemia may thus result. As a matter of interest we would note that rickets, which is considered one of the factors in the production of epilepsy, has often associated with it chronic dilatation of the stomach. Furthermore, Bouchard, in his well-known work on "Auto-infection," lays great stress on the chronic toxemia resulting from chronic dilatation of the stomach. I am thoroughly convinced that many cases of disturbances of the nervous system, chorea, so-called idiopathic epilepsy, and other nervous conditions commencing in early childhood, can often be justly imputed to this type of chronic toxemia. Derangements of the liver and renal functions are often associated, or result from gastro-intestinal disturbances, and take an active part in the toxemic process. Fortunately, beneficient Nature steps in in many cases, and the toxins are eliminated, with no permanent harm to the patient; while other cases may suffer from continual absorption, from prolonged constipation, for example, without any symptoms whatsoever. There is a great difference in the individual.

I should now like to call to your attention some interesting data regarding epileptiform attacks in adults. Mangelsdorf, of Bad Kissingen, has examined over four hundred cases of epilepsy and several hundred cases of migraine, and has found acute dilatation of the stomach, just preceding or during the attacks. He made accurate drawings, in many cases, of the extent of the dilatation. Another interesting type, is gastric tetany, in which gastric dilatation is a factor. Smith[1] reports a case in which a patient with dyspepsia and gastro-intestinal flatus failed rapidly in strength, and became troubled with insomnia. Tetanic attacks occasionally occurred, in which the fingers were forced into the palms. There was trismus, and the wrists were extended and rotated outward. The patient suffered mentally, and sleep was disturbed by spectral delusions. The stomach was found to be dilated, and in a condition of ptosis, and the patient became eventually extremely asthenic. These recurring attacks were entirely relieved by lavage and non-nitrogenous diet, but when these measures were neglected, symptoms at once showed themselves. Dujardin-Beaumetz[2] reports a case of gastric dilatation with very similar symptoms; and Strong[3] describes seven cases, characterized by spontaneous intermittent muscular contractions, and remarks their similarity to epilepsy. Simpson[4] and Kussmaul[5] find tetany a fairly common accompaniment of dilatation of the stomach. Moynihan[6] believes it to be not very rare, and what is of extreme interest, reports five cases in which gastro-enterostomy was performed, with a resulting cure in each case. This is most significant, as thorough drainage of the dilated stomach, the source of auto-infection, was removed and the patients were cured. The brilliant surgical work of Mayo among the nervous and insane is doubtless familiar to you.

I believe that, in certain cases of marked dilatation, or ptosis of the stomach with resulting auto-infection, the field of surgery will in the future play an important part for the relief of nervous and mental diseases. Bouveret,[7] Ewald,[8] Fleiner,[9] Einhorn,[10] and many others have reported cases of gastric tetany. Amato[11] reports a case of gastric dilatation with tetany, resulting in death. He has introduced fermenting materials into the stomachs of animals, and produced dyspnea, myosis, muscular contractions and trismus. The liver and pancreas (post mortem) showed lesions such as are usually found in poisonings and intoxications.

An interesting case of catalepsy, associated with tetanic spasms, has been reported to me by Dr. John C. Minor, of New York. The patient suffered from chronic dilatation of the stomach with ptosis of the organ. Following an attack of constipation, or marked indiscretions of diet, she would suddenly become absolutely stiff, with flexion of the limbs, the eyes tightly closed, and

would remain unconscious for a number of hours. From this condition, as she emerged into consciousness, the feet would extend, the knees increase in flexion, and there would be spasmodic twitchings of all the limbs. Between attacks, the bowels would remain extremely loose, there being many watery movements during the day. As the attack was wearing off, watery movements would occur—as many as twenty in number. While the patient's bowels remained loose, no attacks would occur. A contributing factor to the gastro-intestinal disturbance was believed to be morphine, of which the patient at times took considerable quantities.

Epilepsy, without question, may be in some cases directly attributed to auto-intoxication from the digestive tract. In the *Medical Record*, January 28, 1905, appears an interesting article by Dr. Wm. P. Spratling, Medical Superintendent of the Craig Colony for Epileptics, entitled "Gluttony, or Food Poisoning, as a Cause of Symptomatic Epileptic Convulsions." I quote as follows: "The first few cases of symptomatic epileptic convulsions that I saw in middle-aged men, in which convulsive attacks invariably followed gross overindulgence in eating and drinking, did not impress me as constituting a class of sufficient importance to warrant their being placed in a group alone. But having seen 18 or 20 such cases during the past two years, I have come to believe that they represent a distinct phase of the subject that is well worth calling special attention to, particularly since they are usually so amenable to treatment; substantially all of them making satisfactory recoveries when treatment is promptly instituted and observed as long as the nature of the case requires.

"The cases of this kind that do not turn out well under treatment are those in which the patient is unwilling to deny himself the pleasures of the palate, except spasmodically and immediately after he has had a convulsion. But unfortunately the lesson learned at such times, is soon forgotten, and all such individuals stand in danger of ultimately becoming confirmed epileptics of the so-called 'habit' type, and to suffer all the mental and physical accompaniments of that affliction.

"Usually those who suffer in this way are between thirty-five and forty-five years of age. Most of them are men of robust, frequently plethoric physique; all are hearty eaters; all lead more or less inactive, indoor lives, and some are heavy drinkers. When the latter factor complicates the case, the prognosis is less hopeful than when there is excessive food consumption only; not because the type of convulsions induced by alcoholic indulgence yields less easily to treatment, but because the drink habit is not so readily broken.

"While it is true, as a general rule, that heredity plays but little part in the causation of epilepsy, when it originates anew after the twentieth year, I have found that it is quite frequently a factor of some degree in the cases in question. It seems that there need not be insanity, or alcoholism, or epilepsy, or some other nervous affection in the ancestors of such cases as these, but a stomach disorder of pronounced type, like an aggravated dyspepsia, may make its influence felt in some obscure way in the offspring.

"A very intelligent professional man, forty years of age, came under my care eight years ago. He was subject to symptomatic grand mal attacks that invariably appeared the day following gross dietetic indiscretion, such indiscretions usually occurring between midnight and 2 A.M. He had a weak stomach and could digest certain foods only. On investigation I found that his father suffered the better part of his life in the same way. The father respected his nutritional peculiarity, but the son did not: so the father escaped anything more serious than a severe, periodic dyspepsia: while the son was threatened with becoming a confirmed epileptic. After having an attack while speaking in a public hall once, he realized his danger, changed his manner of living, and had been free from attacks for five years when I saw him last on November 24, 1904.

"The primary cause of convulsive attacks in cases of overeating and overdrinking in certain individuals seems to lie, first, in a weak stomach, and, second, in some obscure disorder of metabolism. Not only is the amount of food habitually taken by such persons beyond all reasonable requirements, but it is usually of an improper kind, and is taken to gratify what seems to be an abnormal appetite.

"The type of convulsion usually induced is of the *grand mal* variety, though it is not definitely fixed. So long as the attacks remain *grand mal* only, the case is less likely to pass into 'habit' epilepsy than when the type changes. The last case of the kind I saw was that of a newspaper man, thirty-eight years of age, who suffered *grand mal* attacks for some years, but whose dietetic habits were so atrocious that the seizures at the end of that time changed to infrequent *grand* and very frequent *petit mal*, with the result that some mental enfeeblement is becoming apparent, his memory in particular. This annoys him painfully, for in his work a good memory is a necessity. Along with the change in the type of his convulsions have come periods of marked automatism.

"The day before I saw him he had a breakfast of cereals, eggs, fried potatoes, pancakes and coffee; a hearty dinner at noon of a rich soup, chicken pie, several vegetables and pudding, with wine sauce for desert; for supper he had a heavy meat pie, of which he ate heartily, three large baked potatoes, three pieces of apple pie, and three cups of tea; and yet he wondered why he suffered so much from headaches, from his stomach, from eructations of gas and flatulence, and attacks of momentary unconsciousness that

were increasing in frequency, and that, worst of all, were fast undermining his mental faculties. He had written me two letters within a week, one on the day before I saw him, and yet he could not recall my name when I met him.

"While the indications for treatment in such cases are plain enough, they are not so easily carried out. The cause of the convulsions must be sought in toxic states due to faulty metabolism. We must first eliminate waste and toxic products, and then plan a course of treatment which will prevent a recurrence of such products."

In a number of cases of epilepsy, during the past few years, Dr. Wm. H. Thomson has secured brilliant results with the cure of patients, from treatment of the gastro-intestinal tract. In a few instances, gastric analysis showed hyperchlorhydria, while in a number of cases there was hypochlorhydria, with or without gastric dilatation. The treatment consisted in avoidance of red meats, intestinal disinfectants, regulation of the bowels, diet and medication suitable to the individual condition of the stomach, and, temporarily, sodium bromide, combined with antipyrin, to lessen reflex irritability and break the convulsive habit. I have treated recently several interesting cases of epilepsy, which were unquestionably due to auto-infection from the digestive tract. Time, however, will only allow me briefly to refer to one case.

A young man, aged twenty-five years, with a negative family history, came to me for treatment, having had epileptic attacks for about six months. About a year previous to this, he had been in the Philippines, where he had a severe attack of dysentery. Since that time he has been troubled with occasional mucous discharge from the bowels. For some monhts past, however, he had been constipated, belches gas from the stomach, and has water brash and a sour taste in his mouth; the tongue is coated. The gastric symptoms are more marked before his attacks. He has averaged one attack a month for four months, and during the last two months has had seven attacks. The early attacks were between 7 and 10 P.M., but more recently they have been from 4 to 7 A.M. The attacks clearly followed extreme indiscretions in diet, and the mother of the patient (who is a trained nurse), sent him to me for treatment, believing that gastro-intestinal disturbances were the factors in the case. In the early morning attacks, he would be awakened by abdominal discomfort, then the hands would begin to twitch, the wrists and arms would flex, then these would be raised automatically to the level of the head, and he would then become unconscious. The tongue was bitten during a number of the attacks. Examination of the stomach contents showed: Total acidity 120 + free hydrochloric acid, 90 +, a condition of hyperchlorhydria. There was intestinal tympanites, and some odor to the stool. Constipation was marked. The patient was shut off from red meats, smoking and drinking, and placed on a simple diet, especially a light supper. The bowels were freely opened with calomel, and thereafter kept carefully regulated. He was given benzoate soda gr. x t.i.d. for the intestinal putrefaction; and soda bicarb. gr. x to xx t.i.d. an hour after meals for hyperacidity. Soda bromide gr. x four times a day, one of the doses at bedtime, was given to break the convulsive habit. This treatment was continued, but the bromide was gradually diminished, and then finally stopped entirely. For four months he had no attacks. He then ate a large amount of candy during the afternoon and evening, and promptly had an attack early the next morning. Calomel was given, and bromides were begun again, and in a few days dropped. During the next three months, he had three attacks, all following indiscretions in diet, and since then has been perfectly well—a period of ten months so far, by merely taking gastro-intestinal treatment and exercising care in diet. This case would seem to be of interest.

I have noted several other cases, where there was hyperchlorhydria with atony of the stomach, and a number with hypochlorhydria and dilatation.

The question of the etiology of epilepsy is of so great interest, that Dr. Wm. H. Thomson has instituted a general research on the subject at the Manhattan State Hospital, West, Ward's Island, in which in each epileptic patient the organs of the body are examined by the various specialists who visit this institution and abnormalities, if present, are corrected. By this means, we hope in time to secure some very valuable data. In Book I (which I pass around for your observation), you will see our gastro-intestinal history sheets for these cases. These are very complete. Appropriate medication is given, such as may be indicated in each case, antacid or hydrochloric acid mixtures. The bowels are carefully regulated, and lavage is employed, if required. Intestinal antiseptics, such as benzoate of soda, resorcin, soda salicylate, and sulphocarbolate of soda are given. The red meats are omitted. Bromide of soda, with antipyrin, is administered, to lessen reflex irritability and break the convulsive habit. Matzoon is made in the hospital especially for these cases. These patients live as much as possible in the open air, a method which Dr. Dent carries out in fact with all his cases in the hospital.

You will kindly observe the photograph I now pass around for inspection. It demonstrates the position of the stomach in epileptics recently examined. The anatomical regions were marked out in blue pencil on the abdomen of each case and during transillumination of the stomach the outlines were drawn in colored pencil. These markings were redrawn directly from each subject, on paper stamped with a special instrument, giving the anatomical regions. The results secured were as follows: Females, total number,

34 cases; gastroptosis, 16; dilated stomachs, 16; stomach in normal position, 2. Males, total number, 6 cases; dilatation of the stomach, 5; stomach in normal position, 1.

The motor functions of the stomach were examined and the analysis of the gastric contents were made with all these patients. These factors were considered in making the diagnosis. There was abnormal secretion in the stomachs occupying the normal position. These data are certainly suggestive. There has been improvement in some of these cases, but it is too soon to report definite results. Of course, many of these asylum patients are of the worst type, and in some, degenerative changes have occurred in the brain. Nevertheless, even under such conditions, auto-intoxication can be minimized and susceptibility to convulsions can be diminished by proper treatment.

These stomachs were transilluminated with the gastrodiaphane and fluorescein solution. On Card "A" you will see a picture of the new "circumscribing gastrodiaphane," which was especially devised for work in this hospital. On Card "B" is a description of the various fluorescent media employed, also a new method, and devised by the author at this institution.

There seems to be an unfortunate disposition on the part of neurologists to consider various gastro-intestinal disorders, dilatation of the stomach, inordinate appetite, stuffing, bolting the food, etc., to be the result of nervous or mental disease. They forget that bulimia (inordinate hunger soon after a meal), acoria (absence of satiety), polyphagia, etc., are often found in stomach diseases. I think that we have, even at this point, fully demonstrated that, in some cases at least, the gastro-intestinal disturbances may be primary.

You are all familiar with the symptoms resulting from chronic constipation such as headache, drowsiness, inability to concentrate the attention, general malaise, etc. Duprey, in the *Lancet*, 1902, I, 1832, cites the following interesting cases illustrating extreme types of toxemia as a result of this condition:

Case I.—A woman of thirty-five years suddenly became unconscious with rapid and shallow breathing, pulse 96, temperature normal. Examination of the urine showed no signs of nephritis, attention to the bowels was followed by recovery.

Case II.—A young man suddenly became unconscious, but could be roused from his stupor only to talk incoherently and relapse into the unconscious state. Heart, lungs and kidneys were normal. Recovery after free evacuation of the bowels.

Case III.—A child, three years old, with a history of constipation, suddenly expired while playing. Autopsy showed no condition which could account for death except that of fecal distention of the descending colon. Some on the other hand have no symptoms resulting.

Many nervous conditions, neurasthenia, mental depression and melancholia, can be imputed to auto-intoxication. Brokers and professional men, with irregular habits of life, constitute almost a class in themselves. Bolting the food, or excessive eating or drinking, rich food, etc., are factors in the production of hyperacidity, motor insufficiency, dilatation of the stomach, constipation, and auto-intoxication, with resulting disturbances of the nervous system, and the treatment of the gastro-intestinal conditions will rapidly restore the patient's nervous tone in many cases. Mental depression often accompanies, or is a symptom of, toxemia, and this condition may even progress to depressive insanity. Among other symptoms of auto-infection from the digestive tract, are apathy, insomnia, somnolence, and inability to concentrate the attention. Resulting from the auto-intoxication of jaundice, we may have all grades, from mental depression to melancholia and insanity. It may cause coma, muscular twitchings, convulsions and death. Stern [12] reports a case of narcolepsy in which, having excluded syphilitic endarteritis, he imputes the condition to auto-infection, resulting from dilatation of the stomach and hyperchlorhydria.

Hamilton[13] offers the following conclusions, having made a special study of the digestion and urine in the insane: "Varying and fugaceous illusions and hallucinations, pallor, increasing exhaustion, verbigeration, confusion and unsystematized delirium, are due to auto-intoxication.

Auto-intoxication is common in alcoholism and the drug habits. Epileptiform attacks are directly connected with putrefactive conditions in the intestines." An interesting condition, resulting from auto-intoxication, is Graves' disease. I have already referred to the work of Dr. Wm. H. Thomson, "Graves' Disease, With and Without Exophthalmic Goiter." He holds that the toxin is formed first in the alimentary canal, and then remains in the circulatoin on account of disturbance of the thyroid. He describes twenty-eight characteristic symptoms. Many cases of true Graves' disease exist without thyroid enlargement. He believes that implication of the thyroid is secondary, just as is the enlarged spleen in some cases of chronic ague. He has secured some brilliant results by treatment of the gastro-intestinal tract. I have already referred to the suggestive fact that ethylenediamin, a ptomain, found in some cases of dilated stomach, will produce exophthalmos on injection into animals.

Another interesting class of nervous cases, resulting from auto-infection, are those in which ptosis of the gastro-intestinal tract is the primary factor. There are various types of this condition, from those of a mild degree to the extreme condition described by Glénard. With the descent of the stomach and intestines, there is a nephroptosis of the right kidney, sometimes of both, and there may be, in addition, ptosis of the liver and spleen. A review of the etiology is necessary.

In the first place, the vertical stomach is the fetal position of the organ. Examination of infants and of young children will demonstrate, occasionally, a congenital gastroptosis to exist, and in some cases gastroptosis with its associated enteroptosis has been accidentally discovered and has undoubtedly existed for many years, with no symptoms resulting, the patient being in perfect health; but some contributory factor, local irritation, anemia or intercurrent disease may destroy the equilibrium, and gastro-intestinal disturbances, constipation, etc., occur, causing auto-infection, and as a result, neurasthenia. The maintenance of a certain degree of intra-abdominal tension is a factor in preserving the position of the viscera; thus a loss of tone in the abdominal muscles, or absorption of omental, or intra-abdominal fat, may be a factor in the production of ptosis. So also may an abnormal elongation of the mesentery, or an atonic condition of the suspensory ligaments of the stomach and colon. The loss of tone in the stomach and intestines—atony—is another factor in the production of ptosis. I have always believed dilatation of the stomach and gastroptosis to be progressive degrees of atony; that in ptosis of the stomach, the organ was dilated and that gastroptosis might be primary, with enteroptosis a secondary condition; this agrees with Riegel's views. I cited a case in which I was convinced dilatation first occurred, then gastroptosis, and later enteroptosis. Glénard, on the other hand, claims that enteroptosis is invariably the primary condition. The conditions are undoubtedly associated, but I believe that either may precede the other.

It is not the degree of the descent of the lower border of the stomach which constitutes a ptosis. With gastroptosis, the lesser curvature of the stomach descends with the greater and loses its relations to the diaphragm; while in dilatation, the muscular fibers elongate in the vertical direction—the greater curvature alone sinks, and the lesser curvature maintains its relations and does not sink.

The gastric condition may be one of hyperchlorhydria, or of hypochlorhydria, or even achylia gastrica. If the splashing sound be confined to below the umbilicus, and to the left of the median line, and one can determine a floating kidney, we can be sure that gastroptosis is present. In the milder degrees of ptosis, it is not so easy to differentiate between ptosis and simple dilatation; and in this event it may be necessary to employ inflation with air, or transillumination of the stomach.

Undoubtedly many cases of neurasthenia, treated with brilliant results by the Weir-Mitchell rest cure, are the result of gastroptosis. Rest and the putting on of fat to increase intra-abdominal tension are of value in ptosis. Rose's adhesive plaster belt is of service in the treatment of these cases, as it supports the organs and increases intra-abdominal tension. I show you a manikin with the belt applied, and also the plaster-strapping ready cut for use. At the Ward's Island Clinics, we were the first to employ the moleskin plaster for the belt. The zinc oxide on moleskin, 7 inches wide, and manufactured by Johnson & Johnson, is the best for this purpose. In a new work, entitled "Atonia Gastrica," by Dr. Rose and myself and published by Funk & Wagnalls, you will find a full description of the method.

I consider mucous colic to be one of the manifestations of Glénard's disease, and the neurasthenic condition present in the disease, to be the result of auto-infection. These views are given in a paper, entitled "Mucous Colic," *American Medicine*, March 4, 1905.

In conclusion, let me say that many cases of neurasthenia occurring in women are due to auto-infection, associated with ptosis of the viscera; and I have seen excellent results secured from the treatment of the latter condition. In extreme cases, surgical measures, such as revision of the abdominal mucles, with shortening of the suspensory ligaments of the stomach, or gastroplication, as suggested by Dr. Robert T. Morris, would be of value. I have already called to your attention that auto-infection from the gastro-intestinal tract may, in many cases, even when there are organic changes in the brain, create a vicious circle and aggravate the symptoms.

Such derangements of the digestive functions occur in syphilis, from alcohol and from drug habits, as well as in other conditions. For example, I present the following data to you of thirteen cases of dementia paralytica, investigated by Dr. Dent. You will note a diminution in the frequency of the convulsions, and a lowering of the temperature in these cases, resulting from regulation of the bowels and treatment of the gastro-intestinal tract, appropriate to each case.

Dementia Paralytica (Analysis of 13 cases).—Tabetic type, 4 cases; cerebral type, 1 case; hyperacidity, 1 case, with dilatation of stomach slight and commencing; achylia gastrica (functional), 1 case; hypoacidity, 11 cases, with two severe types of chronic gastritis; dilatation of stomach, 11 cases; gastroptosis, 2 cases; chronic constipation, marked and of varying degrees of severity, 13 cases; odor to breath, 13 cases; evidences of putrefactive changes in the gastro-intestinal tract, 13 cases; temperature, no result from treatment, 2 cases (in one of these the temperature was due to foul bed-sores); temperature lowered in 11 cases, and in some very decidedly as a result of treatment, and remained lowered (rectal irrigation was an aid in lowering the temperature in 3 cases); convulsions, none occurred at any time in 7 patients; diminished in frequency in 5 patients by treatment; attack of syncope (equivalent to convulsive seizures), absolutely stopped by treatment, 1 case; died, 1 case.

In Book II, you will find abstracts of each case, with a photograph of the stomach. The data are tabulated on the cover. As intestinal irrigation proved of value in 3 cases. I show you the Kemp irrigating tube (recurrent), which is of service

for the purpose. The outflow is curved and larger than the central flow. It is employed in all of our large hospitals. The continuous bath, as advocated by Dr. Dent, is of great value as a sedative and to eliminate toxins.

Surgery.—I have already called to your attention the brilliant results secured by Moynihan in gastric tetany, through drainage of the dilated stomach by gastro-enterostomy, and hence the prevention of auto-infection, and the cure of his patients. The work of Mayo has also been alluded to. I have spoken of the value of surgical procedure in mucous colic, with its associated neurasthenia. In some of our patients suffering from nervous or mental diseases, with marked dilatation of the stomach and auto-infection, I believe that we should resort to gastro-enterostomy, or gastroplication, after failure of the simpler measures. It will relieve the toxemia and break the vicious circle, thereby ameliorating symptoms, even in the worst type of cases. A case of gastroptosis and dilatation, with nephroptosis of the right kidney, the patient being melancholic, was recently operated on at the Manhattan State Hospital, West, Ward's Island, by Dr. Bickham. There was albuminuria, and congestion of the kidney, and the patient's attention was directed to that organ. I advocated that a nephropexy should be first done, to relieve the existing congestions and for the mental effect.

If mechanical support by Rose's belt and medical treatment of the auto-infection do not relieve the nervous symptoms, gastroplication and shortening of the suspensory ligaments of the stomach will be performed. I believe that in some cases in surgery, we have a brilliant future for the relief of nervous and mental diseases, especially in the types mentioned. The work of Dr. Leroy Brown in his department, gynecology, speaks for itself. Finally, since auto-infection from the gastro-intestinal tract would seem to have such an important relation to these conditions, a new method has been instituted at the Manhattan State Hospital, West, Ward's Island, which I will now describe.

In Book I, on the last page you will observe a gastro-intestinal chart for new cases. I insert a copy of it in next column. On this is placed the mental diagnosis, and also the gastro-intestinal condition found by examination. At the bottom of each chart, a memorandum is made of the treatment and the results. This is bound in with the history of the patient. A duplicate is filed separately, so that at any time, under the various types of nervous or mental disease, we can find the conditions existing in the gastro-intestinal tract, and the treatment employed with the results secured, without reading through the histories of the cases. A special physician is appointed to examine each case on admission, and appropriate treatment is at once instituted. We have certain standard mixtures at hand, an acid hydrochloric mixture with pepsin, and antacid mixture (magnesia usta 3 parts, soda bicarb. 1 part), and an antifermentative mixture (resorcin gr. v, benzoate soda grs. x, sulphocarbonate of soda grs. iii.) Lavage is performed when required. Special cases, such as ulcer of the stomach, etc., are referred to the visiting gastrologist. The bowels are regulated, and hydrotherapy (for which there are all the modern facilities) is applied when indicated. In Book I, I have appended a brief history of a case kept for five weeks in

MANHATTAN STATE HOSPITAL, WEST, WARD'S ISLAND.

a continuous bath. By such means, the influence of auto-infection from the gastro-intestinal tract on each patient is carefully observed. Complete urinalysis, estimation of urea—the presence of indican, etc., is carried out in every case. To my knowledge, this is the first institution in this country which has placed the study of the relations of auto-infection to nervous and mental diseases on a practical clinical basis; and it is from such investigations that we secure results from the science of medicine, and the greatest benefit to suffering humanity.

107 East Fifty-seventh Street, New York City.

Dental School's New Site Bought.—The purchase of a new site for the Harvard Dental School, to be located near the medical school in the Fenway, was the pleasant announcement which Dean Smith made to the alumni of the school at a recent reunion and dinner. Dean Smith also made an earnest appeal for a fund of $500,000, for the erection of a suitable building, and an appropriate endowment, on the ground that the school was really a charitable institution and carrying on a strictly charitable work throughout Boston and vicinity.

SYPHILIS OF THE LIVER, SCLEROGUMMATOUS TYPE.[1]

BY JOHN FUNKE, M.D.,
OF PHILADELPHIA;
DEMONSTRATOR OF MORBID ANATOMY IN THE JEFFERSON MEDICAL COLLEGE; PATHOLOGIST TO ST. JOSEPH'S HOSPITAL, PHILADELPHIA.

ALTHOUGH Fischer[1] maintained that syphilis produced five different lesions in the liver, yet he recognized that the forms are not easily separated from one another. The classification given by Virchow[2] is the one usually accepted. He maintained that syphilis may affect the liver as a diffuse process or as a gumma, or these two may be combined, giving us a sclerogummatous form. Frerich[3] recognized a waxy or amyloid type but this has been excluded by Virchow. It is the sclerogummatous form that will be dealt with here. This paper is based upon a liver obtained at autopsy at the Philadelphia Hospital. The pathological diagnosis was as follows: Chronic ulcerative tuberculosis of the lungs; hyperplastic pleurisy; fibroid myocarditis; hyperplastic splenic capsulitis; chronic interstitial nephritits; miliary tuberculosis of the liver.

Since no lesion in other organs bears upon the matter under consideration the post-mortem findings of the liver and the gall-bladder only will be given. The liver lacked 1 cm. of reaching the costal margins in the midclavicular line, it was slate-colored but had a distinct greenish tinge; the organ was firm and scattered over its external surface were many round or oval grayish areas, varying from 2 to 4 mm. in diameter. They were apparently beneath the capsule which seemed involved, as was clearly shown by section; when incised they were found to extend into the parenchyma of the organ, so far as could be determined, to a distance of about 2 to 4 mm. Over the external surface 5 cm. to the right of the suspensory ligament were two depressed grayish-white lines running nearly parallel with that structure; they were both 4 mm. in width; one measured 2.5 cm. in length and the other 1 cm. The organ was found to resist the knife and the cut surface was studded with nodules similar to those described as being present under the capsule. They resembled miliary tubercules in every respect, although it was quite impossible to remove what appeared to be caseous centers. The peripheries of many of the lobules were easily outlined and were slightly depressed; the depressed parts were grayish-white in color and resembled fibrous tissue. The greenish tinge was more pronounced on the cut surface than upon the external portion of the organ, giving the parenchyma a granular appearance. Near the transverse fissure of the organ was a fibrous mass having a dimension of 1 by 2 cm., which incorporated the bile passages but did not impinge upon the vessels. A probe introduced at the ampulla of Vater would extend as far as the juncture of the hepatic and cystic ducts, where it met with an obstruction and upon dissection of the common duct the lumen was found occluded by the fibrous mass already mentioned. Upon further dissection the cystic duct also was occluded; the right hepatic could not be traced, but the left branch passed near the margin of the fibrous mass. The fibrous nodule extended into the liver for a distance of 1 cm. At no point in the growth could either duct or liver substance be identified, apparently it was fibrous throughout and distinctly circumscribed. The greatest diameter of the gall-bladder was 7.5 cm.; the organ reached 10 cm. below the margin of the liver; was elastic and apparently filled with fluid but the distention was so marked that fluctuation could not be elicited. At the junction of the gall-bladder with the liver was a mass of cicatricial tissue which formed firm adhesions between the two organs. The scar was pinkish red in color and very rough. The gall-bladder was found to contain 225 c.c. of a slightly clouded grayish-tinged fluid; the mucous membrane was covered by a grayish-white semisolid mucigenous substance; when the latter was removed the exposed mucosa was pale and smooth. The walls of the gall-bladder were extremely thin, scarcely 2 mm. in thickness. The peritoneal cavity contained 150 c.c. of a straw-colored fluid.

Cumston[4] maintains that the deep indentations along the anterior border of the organ and the white lines running over the external surface of the liver are characteristic of syphilis, and he holds Virchow responsible for the statement that they occur most frequently in the neighborhood of the suspensory ligament and that the convex surface is a frequent site. After fatty metamorphosis, he says, the gummata are absorbed and replaced by fibrous tissue. In discussing the morbid anatomy of syphilitic cirrhosis of the liver Hale-White[5] says the puckering and the scarring are unlike that of atrophic cirrhosis. In syphilitic disease the scars are big and broad, sometimes one-third of an inch in width; they cut the liver into large areas, as big as the back of one's hand; never do we see the little hobnail projections which are so characteristic of ordinary cirrhosis of the liver. Lazarus-Barlow[6] reports a liver with syphilitic stricture of the bile ducts. The organ was dark green from retained bile and it was almost entirely composed of an enormously hypertrophied left lobe. The right lobe was small and its surface was covered with numerous scars and deep indentations, the seat of old gummata. One mass of fibrous tissue involved the bile ducts; the left hepatic duct was separated from the common by a thin fibrous septum. MacKenzie[7] reported a liver which was uniformly enlarged and had two scars on its surface. The gall-bladder was distended with a colorless fluid and its duct was so embedded in fibrous tissue that the lumen was occluded. He believes that the scars on the surface of the liver are retrocedent gummata and calls attention to the

1 Read before the Philadelphia Pathological Society, Feb. 9, 1905. From the laboratories of the Jefferson Medical College and the Philadelphia General Hospital.

fact that the cut surface of the organ strongly suggests the presence of malignant disease.

In the case herein reported the microscope did not corroborate the diagnosis of tuberculosis of the liver based on examination of the gross specimen. Although the indentations and the scarring already referred to by Cumston, Hale-White, Lazarus-Barlow and MacKenzie, were not evident macroscopically, they are very clear microscopically. The dipping is marked even at points where the underlying parenchyma is not involved. The perihepatitis which, according to some authors, is a frequent accompaniment of this form of lesion and to which Stockton ascribes the pain and the friction, is not marked in this case. The capsule is thickened at points and this hyperplasia is greatest where the fibrous tissue extends into the parenchyma of the organ. The tissue responsible for the thickening is composed of coarse wavy fibrils which react to Mallory's reticulum stain in a manner similar to the fibrils making up the normal capsule. Between the fibrils are many lymphoid cells which are evenly dispersed and show little tendency to grouping.

As pointed out by Cumston the fibrous tissue is abundant throughout the sections, and as noted by Hawkins,[9] Quincke,[10] Cumston and MacKenzie, it not only surrounds the lobules but penetrates these structures as coarse and fine strands. The picture presented is such as might have been produced had the newly formed tissue originated at the periphery of the lobule and by continued proliferation gradually extended between the liver cells, and as it did so, impinged upon them, whereby they were destroyed; close examination of the sections stained with Mallory's reticulum stain seems to justify the view that the newly formed intralobular tissue is an increase of the already existing reticulum. At many points it is possible to see how long one side of the blood vessels nests of liver cells have been isolated by the increased reticulum and how difficult it is to outline or even trace the reticulum between the liver cells on the opposite side of the same vessel. In an area where the fibrous tissue is abundant it is evident that toward the periphery of the fibrous mass delicate strands of newly formed tissue surround retrogressing liver cells. The picture presented in many respects is similar to that described as present around some of the vessels. Near the center of the tissue such nesting of the liver cells cannot be found. Here the newly formed tissue is closely matted and between the wavy fibrils are many lymphoid cells. In many places the distribution of the fibrous tissue is similar to that seen in atrophic cirrhosis of the liver, that is, from a central focus, very often a blood vessel; it tends, in the majority of instances, to surround each lobule separately, but occasionally embraces several. A frequent picture is the occurrence of circular masses of newly formed fibrous tissue, the centers of which are occupied by blood-vessels, whose walls are thickened but not in proportion to the thickening seen around the bile ducts; the elastica does not figure in the increase.

Distributed throughout these nodular masses are many bile ducts, the walls of which are also thickened by concentric layers of newly formed tissue. The columnar epithelial cells, fairly well preserved, occur as usual, in a single layer. The circular or perhaps nodular masses of fibrous tissue are responsible for the gross picture which was interpreted as miliary tuberculosis. Although nearly all authors point out that there is an increase in the intralobular connective tissue none refer to that seen around the central vein which, while not marked, is readily demonstrable in the sections.

Adami[11] maintains that in the acquired form of syphilis there is a generalized toxic distribution in the organ with a resulting catarrhal hepatitis which may or may not lead to a general fibroid condition. Flexner[12] is of the opinion that interstitial hepatitis is due to a diffusible poison, perhaps a toxin elaborated by the syphilitic virus or organism. He regards the lesions of syphilis as comparable to those produced by the *Bacillus tuberculosis* which sometimes gives rise to a diffuse fibroid overgrowth at other times produces tubercles. A careful histologic study of the sections in this case lends support to these opinions. The distribution of the fibrosis may be explained in the following way: The toxic substance is brought to the liver by the portal vein and hepatic artery, probably most of it reaches the organ by the former route. We know that the interlobular veins break up into numerous capillaries at the periphery of the lobule which increases the vascular area and this is instrumental in slowing the blood current so that the liver cells at the periphery of the lobule are most severely affected by the syphilitic poison: these cells degenerate or undergo necrosis, the reticulum is irritated, either by the poison itself or by the products of the degenerated cells and as a reactionary process the reticulum, together with the interlobular tissue, is increased.

Scattered throughout the sections, although not numerous, are circular or oval cellular areas which at times involve an entire lobule. They are composed, for the most part, of large cells with palely staining nuclei resembling the hyaline leucocytes; although there are some polymorphonuclear leucocytes present, they are not increased over the number found in other portions of the liver. In the centers of the areas are many granular and fragmented cells and considerable granular detritus; liver cells cannot be identified; here the accumulation of hyaline cells is not so great as farther toward the periphery. Most of the accumulated cells are surrounded by newly formed fibrous tissue except in a number where the encirculating sclerosis is incomplete and the gap is filled by long spindle-cells closely resembling those commonly seen in formative tissue. These isolated patches were at first taken for abscesses but upon finding the polymorphonu-

clear cells as abundant in the liver tissue elsewhere their presence was looked as being incidental. Bacteria could not be demonstrated. Closer study suggested miliary gummata.

Marchand,[13] when speaking of the cellular infiltration of syphilitic livers in infants, tells us, that although the greater number of cells are mononuclear many are polymorphonuclear. According to this author even if the polymorphonuclear cells had not been found in the other parts of the organ their presence need not rule out miliary gumma. Hawkins maintains that miliary gummata are rare, whereas Quincke says they are less frequent than the diffuse form, but when found they are scattered throughout the liver in abundance and resemble tubercles or neoplasms. He notes that deformity of the organ is less likely to occur in the miliary than in the gummatous form. Adami found giant cells among the leucocytes in the small gummata, while Einhorn[17] noted the presence of granular detritus, fat globules, few nuclei, nuclear fragments, and occasionally connective tissue fibrils. The capsule, he says, is made up of scar tissue. Fat was not demonstrable in these sections, but this fact does not imply that it is absent, as not until the sections were examined microscopically was the true condition of the specimen recognized and since the tissue was not fixed in osmic acid the fat was dissolved during preparation.

Incidentally it may be mentioned that the sections also show a moderate amount of pigmentation near and around the central veins where more or less congestion is present.

Sections taken from the fibrous mass at the junction of the hepatic and the cystic ducts are entirely composed of dense wavy fibrils of connective tissue containing many lymphoid cells principally diffused throughout the fibrous mass; occasionally they form mantels around the blood vessels. The nodule contained no recognizable liver substance nor were there any ducts found. Although not found at the usual site for gumma, nevertheless the fibrous mass was taken to be a retrocedent and cicatrized gumma. Adami refers to gummata occurring in the region of the gall-bladder, and Marchand in his studies of syphilitic livers in infants found cellular infiltration around the vessels at their entrance to the organ. Reference has already been made to the case reported by Lazarus-Barlow who believed the occlusion of the hepatic duct was due to the organization of an old gumma. In MacKenzie's case the cystic duct was so occluded that the bile could not be made flow by pressure upon the gall-bladder. The miliary gummata in the present case are in all instances of recent origin and it is very difficult to believe that they are due to the same infection which gave rise to the gumma at the cystic and hepatic ducts. It is fairly well established that a second syphilitic infection may occur in the same individual and this may account for the presence of the recently formed gummata. This view is suggested because sometimes miliary gummata of recent origin are found in the masses of old fibrous tissue which have degenerated and become necrotic just as the liver tissue or the reticulum of the organ in this case.

The greenish tinge of the liver, skin, conjunctiva and other organs mentioned in the post-mortem protocol can be explained by the fact that the bile ducts are extensively involved by the fibrosis, and obstruction must have been present.

Fournier[14] maintained that he never failed to find ascites accompanying syphilitic disease of the liver, but Trinkler[15] says in some cases it is absent. This, to a certain degree, depends upon the involvement of the blood vessels, especially the extent or as has been maintained by some authors, associated irritation or actual inflammation of the peritoneum. The accumulated fluid found in the gall-bladder at autopsy was attributed to the tuberculous condition of the liver with secondary involvement of the walls of the gall-bladder; sections of this organ show no conspicuous change in the wall, no gummata, and therefore the hydrops felleæ seems to have resulted from irritation incident to obstruction of its duct.

The time intervening between the infection and the development of the lesion in the liver has been much discussed. Adami states that in acquired syphilis of the liver we know little about the effect upon the organ during the secondary stage, but judging from the lesions seen in infants with the acquired form of the disease there is a general intoxication which results in a catarrhal hepatitis. Hilton Fagge[16] reports a case with a history of a syphilitic rash, falling of hair, macular syphilides, jaundice, unconsciousness and finally death. Although a microscopical examination of the sections of the liver was made, he says, there were present only such changes as could be attributed to a general toxic condition of the organ. Cumston maintains that the liver is not affected until at least five years after the infection, but may become involved as late as ten or twenty years.

Burlington Commencement.—The annual commencement exercises of the medical department of the University of Vermont were held at "The Strong," June 28. Those to receive the Faculty prizes were: A. W. Bridge, of Burlington, Vt., first prize; Leon L. Lawson, of Nicholville, N. Y., second prize. Awarded for the highest rating during the entire four years' course.

SOME REMARKS ON SUDDEN BLINDNESS FOLLOWING ORBITAL INJURIES. REPORT OF CASE.

BY H. B. DECHERD, M.A., M.D.,
OF GALVESTON, TEXAS.

From ancient times to the present there have been reported many cases of sudden blindness following injuries which involved the orbit but not the eyeball itself. These injuries may take the form of blows or falls upon the orbital margins (with or without demonstrable fracture) or upon other parts of the skull (contrecoup), penetrating wounds such as gunshot or punctured wounds with canes and umbrellas; and occasionally result from falls upon other portions of the body, as upon the feet or buttocks.

Nature of Blindness.—This may be: (1) Immediate and permanent; (2) Immediate, but may improve; (3) A subsequent feature to the injury; (4) Immediate, almost complete, and gradually progress to complete.

Where the traumatism was directed against the walls of the orbit or neighboring localities, the older observers (and some few even at the present day), attributed the visual disturbance to injury of the supraorbital, infraorbital, nasal, frontal, or other branch of the trigeminal, and not of the optic or oculomotor nerves. Thus, reflexly, through vasomotor and trophic influences, it was supposed that both vision and ocular movements could be partially or completely suspended. This theory, of course, is untenable, for as de Schweintz and others have pointed out, if the cause were vasomotor, the ganglion cells of the retina would be the first to degenerate, and there would be an ascending instead of a descending neuritis. (A similar theory as regards sympathetic ophthalmia has also been promulgated; that this disease is due to reflexes operating through the ciliary nerves.)

The real underlying factor is no doubt a fracture or fissure of the walls of the orbit, involving the optic foramen or sphenoidal fissure, inducing either direct trauma of the optic nerve, or else hemorrhage into its sheath, with subsequent pressure from blood or inflammatory exudate. In the last, *i.e.*, exudate, the onset and progress of blindness would likely be gradual. Laceration of cranial vessels, vessels of the sheath, or of the central retinal vessels might be responsible for the hemorrhage. Should the fracture involve the middle fossa, a direct injury of the chiasm or optic tract, or an extravasation nearby, could easily produce visual impairment of both eyes. As in the case below reported, a localized meningitis might effect a similar result. Furthermore, it is easy to see how a penetrating foreign body might be directed to the apex along the orbital walls, although these are fairly thin. In a living subject, they would doubtless offer even more resistance than in the dried skull. According to Morton, the inner wall is least protected, and unless the force is perpendicular to its plane, it is directed to the apex. Lacrimal sac and ethmoidal involvements are apt to supervene upon trauma of the inner wall. Penetrating fractures of the roof are quite common, and often fatal.

For permission to report the following case, I am indebted to Dr. P. A. Callan, in whose service it occurred at the New York Eye and Ear Infirmary.

Case.—A. M., male, white, aged nineteen years, was brought by his mother to Infirmary at 9.30 A.M., March 10, 1905. Patient seemed in a somewhat dazed condition; and hence could not give an intelligent history. His mother stated that on the evening of March 9, at 8 o'clock he had been punched in l. eye with the ferrule of an umbrella. (Three days later, he stated that he was standing on the step of a street car, and that someone in the crowd on street corner punched him in l. eye with an umbrella, latter being directed somewhat upward.) Patient appeared very much depressed. Began vomiting while being examined. Epistaxis from left nostril.

Present Condition.—Left eyeball very prominent. Lids edematous, discolored, ecchymotic. Conjunctiva of lower lid markedly edematous. There is a punctured (lacerated) wound in lower lid, 1 cm. in horizontal length, 1½ cm. from inner canthus, and 1 cm. from lid margin. Pupil somewhat irregular and dilated (7 mm.) Only consensual reaction present. Fundus: Disk margins somewhat blurred. Veins larger than normal and tortuous. Vision-figures at about 20 cm. (?) Ptosis and limited movements. Physical examination negative.

March 10.—Since admission has been in a state of semi-stupor. Gives incoherent answers to questions. Retains no food. Does not complain of pain. Temperature 6 P.M., 101° F., pulse, 76; respiration, 24.

March 11.—Slept only at intervals during night. Seemed dazed, and wanted to get up and walk floor. Restless, tossing from side to side. Temperature, 8 A.M., 100° F. Condition of mind improved; more coherent. Retains some nourishment. Neck very stiff.

March 12.—General condition better. Less stiffness of neck. Excruciating pains in back on attempting to sit up in bed. Chemosis and discoloration of lids and conjunctiva more marked. Retains nourishment.

March 13.—Temperature, 4 A.M., 100.4° F.; pulse, 58; respiration, 18.

March 14.—Complains of moderate frontal headache. Had restless night, sleeping very little. Pulse slow since admission; still slow in proportion to temperature. Wound in lower lid almost healed.

March 15.—Temperature, 4 P.M., 102.6° F.; pulse, 60; respiration, 24. Condition about same; mentally slightly improved.

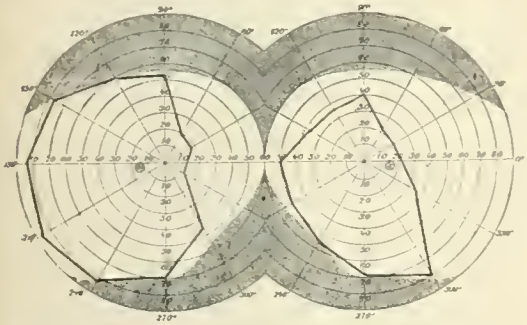
March 16.—Very restless night; tossing about and sitting up in bed. Temperature, 8 A.M., 99.8° F. Pains all over body. Neck still somewhat stiff.

March 17.—Temperature, 8 A.M., 99° F.; pulse, 60; respiration, 20. Feels more comfortable. Tension slightly minus. Only consensual pupillary reaction.

March 18.—General condition greatly improved. Temperature normal. Swelling and edema much diminished.

March 20.—Slight pupillary reaction to direct light stimulus. Fundus examination of O. S. shows lessoned inflammatory reaction, and on exaggerated scleral ring. O. D. shows beginning descending optic neuritis.

Fig. 1.



March 21.—Neuritis O. D. more marked even than in O. S. at earlier date.

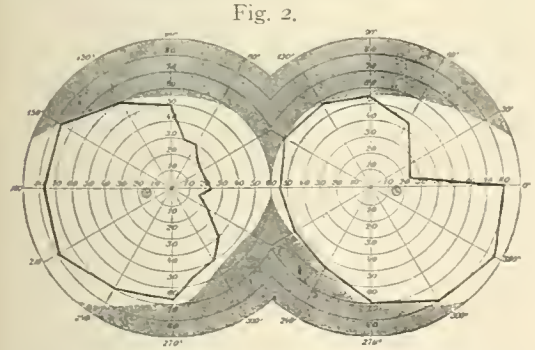
March 23.—Veins enlarged and tortuous in O. D.; swelling of nerve fibers.

March 28.—Disk O. D. clearing up. Disk O. S., beginning pallor; margins of disk easily seen; hardly any signs of neuritis. V. O. S. = 6/60; V. O. D. = 6/5.

March 30.—Margins of disk of O. D. no longer blurred. Left nerve head getting paler. Vision O. N. same.

April 3.—Patient much improved; feels quite well. V. O. S. has temporarily improved to 6/30. Fundus O. D. nearly normal. Discharged. Told to return to Outclinic once weekly for observation of O. S.

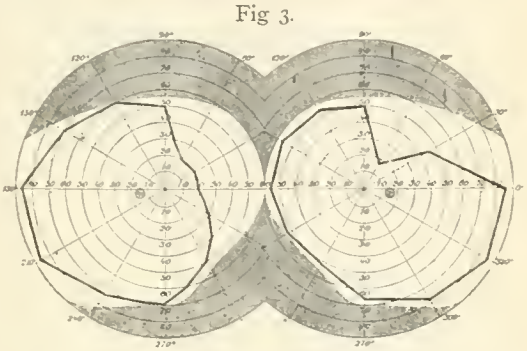
Fig. 2.



Diagnosis.—Separation of fronto-ethmoidal suture into optic foramen (left side), causing pressure on optic nerve, with hemorrhage and localized meningitis inducing neuritis in both eyes.

That so few of these cases are correctly diagnosed is surprising, after a perusal of Callan's and Von Holder's statistics. The former cites 25 occurring in his own practice, with autopsies on three. He thus explained the nature of the traumatism: "The frontal bone unites with the nasal, maxilla, lacrimal and ethmoid bones by a continuous line of sutures, until the lesser wing of the sphenoid is reached; and at this point the suture line bifurcates, forming an obtuse angle. Quite near the apex of the angle is the foramen opticum. The jar made by the blow would find

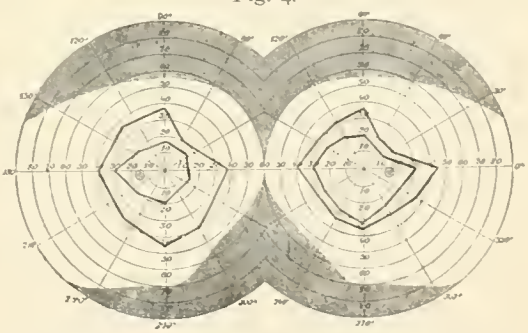
Fig 3.



its weak point along this line of sutures; and the first resistance would be at the bifurcation adjacent to the foramen opticum. The movement or jar could not follow both lines with equal force at and beyond the bifurcation; consequently the unequal strain would result in fracture of the bone into the foramen opticum, causing compression of the optic nerve and sudden loss of vision in the eye."

Berlin, quoting Von Holder's 124 cases of skull fracture, found 86 of the base; 79 of these were through the orbital vault, 63 involving the optic foramen. The fracture was always through the upper wall, and sometimes also through the inner wall of the foramen. In 42 there was

Fig. 4.



hemorrhage into the nerve sheath, but never without fracture of the bony canal. Hence, it can be inferred that in many skull-base fractures, involvement of the orbit escapes notice entirely, either because the patient dies and the autopsy (if any) is not thorough; or also because the other symptoms mask those of the eye. Later on, when atrophy is discovered, it is usually ascribed to some other cause than fracture (reflex; direct injury to nerve, etc.). In addition to the cases already noted, Hewitt (System of Surgery) notes 68 fractures of the base, 23 extending into the orbit. Indeed, fracture of the

walls of the orbit, usually involving the optic foramen, have, on close clinical study and post-mortem investigation, so often been found to be the basis of sudden blindness following orbital injuries that it may practically be regarded as a *sine qua non*.

For fields for March 21, 27 and 31 (Nos. 1, 2 and 3) are shown in accompanying diagrams. On April 12, an attempt was made to take the color fields (No. 4). White (the outer field) is fairly accurate; but the fields for blue, red and green, could not be distinguished with certainty, all seeming to have about equal dimensions (inner field). The constrictions of the fields correspond of course to the situation of the nerve fibers most affected.

THE SEXUAL NECESSITY.[1]

BY E. L. KEYES, M.D., LL.D.,
OF NEW YORK.

I HAVE been allotted ten minutes and asked to present briefly a medical point of view, a suggestion as to the lines along which this Society shall approach the community in an educational way—for this is an educational symposium. And it seems to me that I may do this best by attacking the matter at its kernel.

The gist of the whole subject, as I believe, lies in the sexual problem, a problem we usually discuss behind closed doors; but the doors must be opened now if the Society expects to accomplish anything educational. The dissemination of knowledge along pathological lines will doubtless be helpful in deterring the stupid, the ignorant but innocent and right-minded from spreading disease through the community—that is the correction of such obvious and widespread errors as a belief that the danger of communicating syphilis ceases upon the cicatrization of the chancre; the old, oft-quoted fallacy that a gonorrhea is no worse than a cold, the belief that a mild gleet is no longer contagious; and, finally, the most abominable of fallacies that a proper treatment for a mild gleet is sexual intercourse—even matrimony.

While a broader knowledge upon all of these points is most essential to the community in its own interest, yet this does not hit the root of the evil which, in my opinion, is the dual standard of sexual morality for the two sexes, based largely in modern days upon the idea that sexual exercise is, on the whole, sanitary to the male, if not essential to the best performance of his other general physical functions and necessary for the preservation of his sexual potency.

This idea, upheld by a considerable minority at least, perhaps by a majority of the medical profession, as well as by a large contingent of the laity in a loose way—this idea, I repeat, is the nucleus of the whole matter—and it is this idea that I propose to discuss.

From a medical source should come some authoritative utterance in controversion of this fallacy upon which, as a foundation, the lay educator may build—amplifying and elaborating his superstructure to any extent.

The early man probably obtained his wife by physical prowess and held her in subserviency, he doubtless doing the fighting and the bread-winning and she ministering to all his needs and wants, more as a favored servant than anything else. He was prince and she was subject to him. The right of man to exact sexual tribute from the weaker sex appears to have been granted as a matter of course. All the histories of prostitution touch upon this subject and make it clear that, in the earlier days in the East, it was considered a part of the duty of the host to provide for the sexual necessities of those to whom he

[1] Read before the American Society of Sanitary and Moral Prophylaxis, April, 1905.

owed the rite of hospitality, even considering it a courtesy to go so far as to offer his daughter for the accommodation of his guest. And this custom in its entirety, I have been told by a guide conversant with the remote regions of Morocco, still obtains in that district to-day.

Man in his strength and physical might, therefore, exercised a power of selection over the weaker sex and appropriated or dispensed the favors of the female at will.

The fighter seems naturally to be sexually overvigorous; the continuous physical worker and the athlete in training not so.

I am told by a general in the United States Army, who has seen a large amount of campaigning among the Indians in our Northwestern country, that, in his experience, the Indian undergoes a period of rut in the spring-time. Then it is that he paints his face, bedecks himself with feathers, and goes upon the warpath; and, when a band has raided a settlement—while the fighting is still going on—the warrior rushes in among the burning tents of the village of the enemy, and at once proceeds to ravage the women.

Women, as a rule, admire a fighter; one who is bold and aggressive appeals at once to them and is granted a favorable reception in a general way, while the feeble, effeminate male is looked down upon and turned slightingly aside.

Moreover, it is the well-known habit of the community to look leniently upon the sexual errors of the male, while those of the female are frowned down upon with unrelenting severity—as if to say, the lily once smirched is ruined forever, while the coarser fiber of the oak leaf may receive many a bruise and still be accepted by the community. This is illustrated forcibly by the popular sentiment existing to-day in the South. If a black man is known to have sexual relations with a white woman, he is run out of the town and fortunate if he escapes lynching. But if a black woman seduces a white boy, the matter does not appear to be so serious—lynching the woman, at least, is not one of the sequences.

In the same way, any jury in the North will deal gently with the man who shoots at sight the villain who has seduced his wife or daughter; but no one thinks of shooting the woman who, by her wiles, has seduced his son.

This spirit of recognizing a certain sexual right on the part of the male, therefore, still exists and is accepted and tolerated by the community as a whole—not by the church, not by the law, not theoretically by the community—but practically it is a fact that it is so tolerated.

How then is this sentiment, this tradition, this unwritten law to be overcome? Only by educating the young male, teaching him to develop his character, teaching him that his sexual yearnings are to be restrained like his propensity to overeat, to overdrink, to overexercise; teaching him that because he wants a thing it is not, therefore, necessarily good for him that he should have it, but often harmful; by assuring him that not only will he not perfect or retain his sexual potency by indulging in illicit intercourse, but that he is more likely by excess and irregularity to impair it—and this information it is the province of the medical profession to impart, and to impart it forcibly, speaking as a unit and with no uncertain voice.

But how shall we prove this last proposition upon which there are held diametrically opposite opinions in the profession? There is not time nor would there be much purpose in appealing to many authorities. I shall cite two, however, as types.

Milton, in his work on gonorrhea, boldly states that sexual intercourse is necessary for the preservation of the sexual function. He takes the broad stand that any organ, not exercised, gradually but necessarily loses its power, and that impotence is the direct consequence of continence—of course citing cases.

Acton, On the Reproductive Organs, on the other hand, with equal insistence claims that absolute continence is compatible with perfect preservation of the sexual function and, equally, cites striking cases in proof—and so on through the list of authors.

Is this expression of opinion then a matter of personal point of view? I think, manifestly, yes.

Anyone reading Milton's book is at once struck by the force, the vigor, the rankness of his style. Here is a physical man rejoicing in the air he breathes, the food he eats, in every vital act. He was, doubtless, full of physical necessity and recognized, as many stalwart young men certainly do, a consciousness of physical comfort, a clearing out of the cobwebs of his brain, a sense of bien-être, when following a regular and systematic sexual life, that was absent when his sexual relations were interrupted. There are many, very many, such individuals in the community; and if they cannot marry, they habitually resort to illicit connection and, because they feel better after the act, persuade themselves that they cannot live without it; and this is particularly true if they allow their imaginations to have full play.

Read Acton's book, on the other hand. Here is an intellectual type. He is no gross feeder and is not in any sense carnally minded. His delights are in the pleasures of the mind and the soul—and yet he is forceful, shows character, and is surely a manly man.

So one gets a few cases that support his thesis and generalizes from them; and the other does the same. Which is correct?

But now, leaving generalities, let me resort to the direct appeal.

One of you, gentlemen, has a charming daughter. She is delicate and refined, sensitive, emotional, but pure in heart and has no thought or suspicion of any sexual appetite, desire, or neces-

sity. She has reached the age of—let us say thirty years, and you recognize that, slowly but surely, her virginity is crystallizing and that she is getting angular in mind and body; opinionated, narrow, discontented—in short, that she is becoming an old maid. She does not know it; but you do. She is suffering from balked maternity.

Now, put yourself the question; you who, in the case of a young man apparently suffering from distended seminal vesicles or the teasing of insistent sexual desire, are perhaps willing to suggest sexual intercourse—would you brutally say to this fair sufferer—go and get a man? God forbid! Rather let her suffer; rather let her die, if need be, than debase herself and sully her vestal purity.

And why should not the same standard be held up to the boy? Why should not he be helped to form character by resistance and to cultivate manhood by honest purity of mind and body? For it is the imagination that does the mischief. Except in case of disease or strong inherited tendency, the sexual appetite is not insuperable. Very many honest citizens reach manhood without ever having practised sexual intercourse and are none the worse for it. Most of these have had nocturnal emissions and very many, it must be admitted, have practised self-abuse more or less; but the braver and purer minded among them are not injured by these occasional lapses from integrity and, if their minds are kept reasonably clean by manly exercises and outdoor sports, they are not in the least degree menaced by impotency. On the contrary, impotence, nervous or real, is vastly more often the result of sexual excess than of sexual continence, as the case-books of any practitioner interested in genito-urinary work will attest.

The testicle is a gland like the tear gland, largely under the control of emotional influences. It is not concerned in the ordinary actions and doings of everyday life. That one, by practising the emotion of grief or sadness and weeping copiously once a week or oftener may learn to perform the act of crying more creditably than some harder-hearted individual, I will admit; but this individual would not lose the power to cry even if he did not exercise it for half a century.

And, finally to leave the theory and opinion and come down to a matter of hard fact, capable of physical demonstration: It may be safely and surely affirmed that no amount of continence ever caused atrophy of the testicle.

Now, if continence, too long continued, can produce impotence, that fact should be evidenced by a wasting of the testicle. And I confidently assert that this is never the case; nor has anyone, to my knowledge, ever claimed it to be so. On the contrary, atrophy of the testicle, to a greater or less extent, very often follows prolonged sexual abuse and excesses—notably those of masturbation, because the latter are more excessive. Indeed, throwing the testicle wholly out of function forever in a physical way—as occurs after the blocking up of the excretory duct on both sides in double gonorrheal epididymitis—does not produce atrophy of the gland, as all physicians know perfectly well to be the case.

If there is anything more pitiable in life than the young sexual neurasthenic, debilitated by sexual irregularity and excess, it is the old man, the victim of years of irregular and illicit indulgence, whose mind still gloats over forbidden pleasures which his body can no longer gratify. Death is his best friend to terminate an unhappy and polluted existence.

If the youth, sowing the wind, could appreciate fully the whirlwind he is likely to harvest, it would stay him in many a mad act and conduce to the salvation of his body as well as of his soul.

SOCIAL PROPHYLAXIS AND THE CHURCH.

BY REV. HENRY A. BRANN, D.D.,
OF NEW YORK.

The menace to the very existence of the human race necessarily implied in the dreadful and loathsome disease which your honored and learned society exposes and opposes, has always met with powerful opposition from the Church. It could not be otherwise, considering that the Church hates and tries to counteract the vice which is the root of the disease; and that the human body, which is a necessary part of man, comes next in importance as an associate and partner to the human soul in the mind, in the theology and in the practice of the Church. Not only is it part of her divine mission and occupation to practice the spiritual works, but also and consequently the corporal works of mercy; and the sick of body, whether from their own fault or from the fault of others are special objects of her tenderness and care.

To the special form of disease in which your Society is so deeply interested she has always opposed the antidotes within her competence. But she has not yet exhausted either her power or her influence. One of the most important helps that she could give to society would be to make antecedent syphilis an impediment diriment of marriage. At the present time it is not such an impediment; but if it is clearly proved that the syphilitic directly endangers the life of the non-syphilitic contracting party and destroys the life of the offspring, the case would easily come into the category of matrimonial impediments, all of which have moral and social reasons for their existence. If consanguinity and affinity to the fourth degree inclusive, for social reasons, have been made impediment, there are reasons why syphilis should take rank in the category. That it is a reason for separation of the parties after marriage no one questions; particularly, if the syphilis be produced by the infidelity of the party suffering from it. No man or woman is compelled to live with an unfaithful partner, whether diseases follow the act of infidelity or not. Thus holds the Church and to this extent

at least she punishes the culprit and protects the innocent.

But even if the Church made syphilis an impediment diriment of marriage, the remedy would still be only partial and limited. The Church's law would be accepted only by her faithful adherents. Those not faithful or those rejecting her authority would still remain in the syphilitic zone; and no human power could completely limit their corrupting action. Still, even any limitation of the scourge would be a great benefaction for humanity.

Certainly the Church tries to eliminate the scourge. Her whole moral code and her sacramental system aim specially at the destruction of the vice of impurity which is the root and the fountain of disease. She holds up to young and old models of purity for imitation, particularly the fair white rose whom the poet calls "our tainted nature's solitary boast." Convinced as the Church is that education and knowledge alone are not adequate remedies, for experience shows that the medical schools, which have the greatest knowledge of the disease, are not immune from the vice which generates it; she insists on the special inculcation of the principles of morality and of purity in all her schools for the young. Nor does she stop at mere teaching in school.

She periodically during the year often separates the sexes, and gives to each lessons of warning regarding the dangers of the venereal scourge with which God smites those who violate the laws of purity. In every school of boys; in every school of girls; in every church during periods of retreat special instructions, admonitions, warnings, are given regarding the mental and bodily diseases consequent on sexual abuse.

The "missions" which are constantly given in our churches; the "retreats" given to women in convents, and to men in churches and colleges, are always opportunities which the clergy use to point out the dangers, physical and moral of impurity; and the plainest language is used so that there is no lack of knowledge on the subject.

As much depends on the conscience and on the strength of the individual's will, the Church tries to form and develop the one, and to strengthen the other. She trains the individual from his earliest years to loathe and shun the vice of impurity; and the occasions which lead to it; and both by word and example encourages him in the struggle against impulse and evil inclination. If he is weak, if he pleads weakness, she strengthens him by calling his attention to the fact that he is a free agent and that no internal or external temptation has the power to coerce the free human will. She reminds him that he is a free agent and tells him in his trials to call on the supernatural aids which are always ready for the Christian in prayer and in the sacraments. Constant prayer and frequent reception of the sacraments are her most potent factors in the prophylaxis of the individual and of the family from contamination and infection.

But the Church does not confine her action in this regard to mere instruction or warning. She does not try to protect social purity merely by strict surveillance over the conduct of the sexes in their relations to each other; and in their separate and isolated relations in schools and colleges; but she applies what I think is the most efficient remedy in the world for the elimination of diseases resulting from social impurity.

This remedy is the confessional. All who know the meaning and the power of the confessional will understand what I mean by this remedy. She claims it to be an institution of divine origin, the aim and purpose of which is to absolve the duly penitent from sin; and there is no faithful son or daughter of the Church who does not use this institution; and the most faithful Christian is the one who uses it most frequently. The little child from the age when he begins to think evil is taught to confess his sins in a tribunal, where sits a man who is at the same time a judge, a physician and a father. This man known as the priest is to warn the penitent against the first erotic impulse, the first impure thought, and tells him plainly, although not so explicitly as the physician, the physical dangers of the vice to which he is exposed. And if he fails and becomes the victim of passion, the priest consoles him, strengthens his renewed resolutions and passes him over to the physician for physical treatment. There is no priest who has experience but will tell your honorable society what every penitent knows, that a man will never become a syphilitic if he frequents the confessional and uses the means therein suggested! Nor will anyone with a Christian conscience, suffering from an infectious disease, enter into marriage, and he will certainly have this conscience if he goes to confession and obeys his confessor.

But even with all this teaching and practice, syphilis will be propagated; for the teaching of the Church and of all the professions does not control the majority, even of that part of the human race which is called Christian. The Church, however, will do her part in the great work which you are trying to accomplish and is always ready to cooperate with a profession which she has always loved and cherished; a profession that shares with her the credit of having done so much to relieve physical and mental infirmities. In protecting the sacred body of man from disease begotten of crime, the Church is the close ally of the medical profession; and both will ever work together for the physical and moral good of society.

Acute Carbon Bisulphide Poisoning.—ALBERT P. FRANCINE (*Am. Med.*, May 27, 1905) reports a case occurring in a man aged thirty-seven years, who was employed in a mill where carbon bisulphide was used in the manufacture of artificial silk. Up to the present time but few cases have been reported in American literature.

MEDICAL PROGRESS.

SURGERY.

Incontinence of Urine.—E. C. DUDLEY (*Journal A. M. A.*, June 3) describes a new operation for the relief of the urethrocele with imperfect urinary control, sometimes met with in multiparæ. It is based on the same principle as the operation of Albarran for the same purpose; the urethra, however, is not dissected free and the danger of its sloughing is avoided. The first step consists in denuding a horse-shoe-shaped surface between the meatus and the clitoris, and to either side throughout its length. In the second step of the operation the meatus is drawn up to a point near the clitoris and secured there by means of two sutures. The lateral portions of the denuded surface are then closed. The first two sutures stretch the urethra upward toward the clitoris, and the lateral ones tend to hold it in its new position. The idea is to straighten the urethra by longitudinal tension and to collapse it and to hold together the dilated walls and to overcome the sacculation at the neck of the bladder by traction. In many cases it may be necessary to operate at the same time for the associated cystocele, and in nearly all cases to perform perineorrhaphy for the relaxed posterior vaginal outlet. When there is very much relaxation of the tissues about the clitoris, and there is danger of it being pulled down, he would take a reef in the tissues above that organ, enough to keep it sufficiently high to hold the urethra taut. He has performed this operation five times since January 1, 1905. In the first four, the relief was immediate, and, so far as known, continuous. The last case is still too recent to be correctly estimated.

Value of Edebohls' Operation in Nephritis.—Decapsulation of the kidney behaves in many ways like a benesection: The operation itself is very bloody and increases the flow of blood within the kidney itself in the parenchymatous forms, while in the interstitial type a certain amount of pressure is taken away from the vessels, and the blood can more readily enter and leave the organ. Since most of the lesions must be ascribed to deficient blood-supply, it is evident that the process will be favorably influenced. In uremia, decapsulation will also do good, since the increased blood-flow will tend to remove waste-products. If the exciting causes of nephritis (lead, uric acid, alcohol) are kept out of the body, and sufficient healthy renal tisue is left, a cure may follow the operation. In the three cases of W. SCHEBEN (*Münch. med. Woch.*, May 9, 1905) the most marked sign of improvement after the operation was diminished excretion of albumin; the edema disappeared somewhat later.

The Operative Treatment of Fracture of the Patella.—Since the advent of aseptic surgery the treatment of fracture of the patella by the operative method is daily gaining more advocates, and is followed by better functional results than it was ever thought could be obtained by non-operative methods. H. M. RIGBY (*The Practitioner*, May, 1905) strongly advocates the wiring of every fracture of the patella unless there is present some definite contraindication. This view is taken as a result of a series of twenty-one cases operated on by the author during the past four years. Under the old treatment, by strapping, extension, splinting, etc., an average period of at least six weeks was spent in bed with the leg on a splint, and this was followed by a tedious out-patient treatment for several months. Finally, at the end of six or nine months, patient was left with a partially stiff knee, and was quite unable to follow any laborious occupation. By the operative treatment the patient remains in bed for a period of a fortnight after the operation, and for the first ten days the leg in kept in a splint. After fourteen days the patient is able to get up; he leaves the hospital at the end of three weeks and, as a rule, can walk without artificial aid. In six to eight weeks he is able to perform his usual work. The author claims that by the operative method: (1) The loss of time consequent upon the receipt of the injury is enormously reduced. A clear gain of at least six months can be figured on in an average case; (2) that the operation ensures sound bony union with a perfect functional result. In all the author's cases the open method of treatment was adopted. This consisted in: (1) Exposing the fragments by an incision which is preferably semilunar; (2) emptying the joint of blood-clot, serum and torn tissue; (3) freshening the surface of the fragments; (4) passing silver wire sutures through holes bored by a drill, and (5) suturing the lateral tears in the expansions of the quadriceps. The results obtained in this series of cases are interesting. In seventeen cases the average stay in the hospital after the operation was twenty-three and a half days. Sixteen of these patients were able to walk out of the hospital without any support, with the power of flexion of the knee to a right angle. Infection of the knee-joint occurred in one case which ultimately required amputation of the leg. In a second case an effusion of blood serum had to be evacuated under anesthesia. And in a third case there followed slight superficial suppuration, which was probably due to a lacerated wound received at the time of the accident.

Peritoneal Gauze Drainage.—W. D. HAGGARD (*Journal A. M. A.*, May 27) calls attention to the fact that the fancied necessity for drainage after abdominal section has been greatly lessened by the knowl- that the peritoneum can easily dispose of considerable amounts of blood and serum and that accumulatins of pus are generally sterile. He calls attention to the likelihood of wound infection from drainage after hernia operations, and to the danger of resulting hernia after infected abdominal wounds, and states that this is infrequent after wounds which have healed asceptically. He advocates drainage through the cul-de-sac of Douglas, and describes his methods in detail. He places the gauze in the abdomen, so that, after the operation is completed and the incision sutured, the gauze may be reached through a new incision in the vagina with less danger of infection

Bronchoscopy for Removal of Collar Button from the Lung.—E. FLETCHER INGALS (*Journal A. M. A.*, May 27) reports an interesting case in which a collar button had remained in the air passages for fourteen months. The fluoroscopic examination was practically negative. Under general anesthesia, a large amount of pus was evacuated, and in it were the remains of the collar button. The patient made an uneventual recovery.

Anchylosis.—J. B. MURPHY (*Journal A. M. A.*, May 20, 27 and June 3) reviews what is known of the embryology and the histologic development of joints, classifies the pathologic modifications of anchylosis, and discuses the formation of synovial sacs and their artificial production and the various tissues involved. The synovial fluid is, he finds, a liquefied collagen, a result of the degeneration of connective tissue, and not, as Virchow taught, a secretion from the surface

of the cavity. This fact is a basal one in the surgical management of capsular or articular anchyloses; another one is the thorough freeing of the tissues so as to allow unrestricted motion of the joint. Murphy believes that the elements that have most contributed in causing failures are the insufficient or defective exsection of the synovial membrane capsule and ligaments and insufficient interposition of fat and aponeurosis, or of fat and muscle, between the separated bony surfaces. After these come infection and sensitiveness to pain, limiting motion after operation. Muscular aponeurosis with fat makes the best interposed tissue; if this can not be had, then muscle and some fatty tissue should be used. Muscle flattens out into an aponeurosis in many joints, but it does not withstand so well the early pressure required for a good result. A number of cases are reported in detail, and, with the elaborate series of pictures, well illustrate these and other points brought out in the article. In conclusion, Murphy reviews the literature of the attempts to produce new joints, and says: "In our work we have been able, by the interposition of fascia and muscle, covered with a layer of adipose tissue, to produce normal movable joints, with capsules and collagen intra-articular fluid. This, we believe, is the first systematic production of new and practically normal articulations."

THERAPEUTICS.

Excision and X-rays Combined in the Treatment of Exophthalmic Goiter.—It is claimed that the pressure symptoms which are such a prominent feature of this disease are caused by an increased blood supply of the thyroid gland. This idea has been applied to the therapeutics of exophthalmic goiter and Kocher proposed that the larger vessels to the glands be tied off and the latter also, partially excised. The results were fairly good, although no effects were noticed at all in a certain proportion of the cases and in other the after effects were most disagreeable. C. BECK (*Berl. klin. Woch.*, May 15, 1905) is convinced, however, that the method should not be abandoned and from this observation with the X-rays on the vascular supply of new growths he is prompted to suggest that a similar effect on the vessels of the thyroid may be produced by the same agency. The final results may be accelerated if in addition one of the lobes of the thyroid be previously excised. In two instances in which partial thyroidectomy was not followed by any result after the elapse of a year or more, the rays were applied and a marked improvement in the nervousness and tachycardia was noticed. In a third case, the Roentgen rays were used immediately after operation with a much more satisfactory result. The sessions consumed at first five to ten minutes daily, and then were given weekly with astonishing effects, so that in five months time the remaining portion of the gland could scarcely be felt and the exophthalmos and the tachycardia had entirely disappeared. The case is of great interest and should animate a more general investigation of the subject.

A New Field for the Roentgen Rays.—GOERL (*Münch. med. Woch.*, May 16, 1905) has made the very interesting observation that goiter is very amenable to treatment with the Roentgen rays. The change set up in the diseased tissue is probably not due to closure of the blood-vessels but is an actual destruction of parenchyma cells, since a diminution of size takes place very rapidly. Soft tubes are generally employed for ten minutes at a time, at a distance of 10 cm. General symptoms, due to disturbed thyroid function, were never seen.

A Further Contribution to the Therapeutics of Iron.—After thorough experiments upon animals in pharmacological laboratories followed by clinical observation, SHEDMAKER (*Chicago Med. Rec.*, April, 1905) states that ovoferrin, a new compound of iron, is the only iron yet produced which meets the requirements established by those authorities from whom were obtained most of the laws governing present-day scientific therapeutics. His clinical observations cover a series of 117 cases, consisting as follows: Secondary anemia from hemorrhage, 8 cases; gastric ulcer, 6 cases; convalescence (from typhoid fever, pneumonia, diphtheria, rheumatism), 18 cases; headache, due to anemia, 8 cases; the anemia of chronic parenchymatous nephritis, 6 cases; incipient pulmonary tuberculosis, 8 cases; neurasthema, with marked anemia, 10 cases; anemia from prolonged lactation, 7 cases; chronic gastro-intestinal catarrh, with anemia, 8 cases; convalescence from infantile diarrhea, 12 cases; nervous school girls, with anemia, 10 cases; malaria cachexia, 4 cases; chlorosis, 12 cases. The author concludes as follows: (1) That a careful study of the authorative researches on the physiologic and therapeutic effects of iron show a well-defined relationship between the chemical constitution of iron compounds and their comparative assimilability and therapeutic effects; (2) that the group of compounds of which ovoferrin is at the present time the only representative, constitute the best method of administering iron in clinical conditions attended with blood impoverishment because (*a*) it is more rapidly and completely assimilated as proved by the greater increase in hemoglobin and red blood corpuscles as evidenced by clinical studies of its effects in comparison with other forms of iron. (*b*) It does not disturb digestion, irritate the alimentary tract or produce constipation. (*c*) It has a noticable effect in increasing the appetite. (*d*) It has in addition to its hematinic action, a pronounced effect upon general nutrition which endows it with value as a general tonic in clinical conditions attended with general debility.

The Antiseptic Properties of Smoke.—The popular notion that fumes of various burning substances have healing properties, is not without scientific foundation. M. A. TRILLAT (*Les Nouveaux Remèdes*, April 24, 1905), finds that the smoke of wood, sugar and various other substances contains an appreciable quantity of formaldehyde gas. Saccharose when burnt yields a smoke that contains a fairly large quantity of this gas. This probably explains the beneficial effects which have been attributed to the smoke obtained by burning raisins or grapes, a practice which is found in the traditions of household medicine, and which may be traced back to Hippocrates. The author found that smoke markedly inhibits the growth of bacteria.

Mercurial Injections in the Treatment of Syphilis.—This subject is reviewed by LAMDIS in (*Gazet. des Hospitaux*, April, 1905) as to method therapeutic action and value. *Methods.* (1) The local or Bouchard's, in which the injection is made into the site of a specific lesion. Under this head come the subconjunctival and subarachnoid injections; (2) the intramuscular injections, the most frequently employed, least painful and assuring rapid absorption; (3) the subcutaneous, which, however, has been almost superseded by the intramuscular; (4) the intravenous, very delicate and exceptional; (5) most recently the intratracheal. Both soluble and insoluble salts and metallic mercury are used. Biniodid and benzoate are most commonly employed. *Therapeutic Action.* A local re-

action is first noticed; pain and inflammation varying with the different preparations used. The specific action is the same as with other methods of administration, but more definite and quicker. It is possible to calculate the amount absorbed. It is customary to inject daily a quantity of mercurial representing .01 gm. of metallic mercury. A possible toxic action due to additions of other substances, to certain forms of mercury (cyanide for example), or to intolerance, must be kept in mind. Absorption is rapid; in the intravenous method instantaneous. Elimination begins early and is the same as in other methods. *Advantages.* (1) Maximum effect from a given dose. (2) Exactness of dosage. (3) Non-interference with the digestive system. *Disadvantages.* General intoxication and local accidents. On account of the rapid absorption it is impossible to counteract intoxication in time. Of local symptoms continued and severe pain, extensive inflammation, and sometimes even a febrile condition are objectionable. *Indications.* (1) Grave complications, such as coma, lesions of vital organs (larynx, ear, eye) and extensive phagedenic destruction call for a method of quick results; (2) when other methods fail to accomplish the desired result; (3) in certain cases, for quickly establishing a diagnosis. Intolerance of the skin and stomach and social conveniences of the patient make injection the treatment of choice.

X-ray Treatment of Cancer.—The microscopic changes in the tissue, says E. G. Williams (*Journal A. M. A.*, May 6), should be our guide as to the therapeutic possibilities in the X-ray treatment of malignant growths. It is evident, he states, that the elements of the tissues are affected according to their vitality. Dead organic matter is unaffected, and the more active the growth the greater the effect. Next to this is the accessibility of the tissues to the rays. Hence the better results with superficial or skin cancers. That moderately deep tissues can be affected is shown by experience, and the way to reach them without producing necrosis of overlying tissues is to lengthen the distance of the tube and the time of exposure. For deep growths, radical surgical measures should be recommended, as the patient should be given the benefit of the probability rather than the possibility of good results. In such cases, however, operation might be rationally followed by X-ray treatment to destroy what may remain of the malignant growth. Inoperable cases should be treated by the X-ray because remarkable results have been obtained and the most distressing symptom of pain relieved.

Protection from Roentgen-Ray Injuries.—C. L. Leonard (*Journal A. M. A.*, May 6) calls attention to the serious risk that X-ray operators undergo, especially if they follow the practice advised of testing the qualities of the rays on their hands with the fluorescent screen. The only practical method is to limit their radiated field by covering the Crookes tube. For this purpose he uses a pasteboard box a little wider than the diameter of the tube and covered with X-ray lead foil a little heavier than the ordinary tea lead. This extends two inches below the bottom of the box, and can be adjusted so as to limit the field to any extent required. It is not necessary to cover the anode end, and the box is held on a bracket over the portion of the body to be treated; if a very small field is required, a local shield may also be employed. He thinks possibly some effects are due to the strong induction field surrounding the coil which, especially in large hospitals, should be kept in another room, but with the controlling apparatus within the operator's reach. For the dermatitis of the operator's hands, he advises twice daily soaking in very warm water and scrubbing with Eichhoff's superfatted resorcin soap, followed by inunction of lanolin containing half an ounce of boric acid and a dram of resorcin to the ounce. For the acute erythema of X-ray treatment, he employs a stearate of zinc powder with 10 per cent. ichthyol, which he thinks acts as a prophylactic against severe burns. This should not be confused with stearate of zinc ointment, which may do harm.

PRESCRIPTION HINTS.

Dysmenorrhea.—In spasmodic and neuralgic dysmenorrhea the following prescription will prove beneficial if administered several days prior to and during the menstrual epoch:

℞ Extracti hyoscyami fluidi.....5ii
Extracti cannabis Indica fluidi.....5i
Extracti cimicifugæ fluidi.....5iv
Spiritus camphoræ 5i
Spiritus etheris compositæ.....q.s. ad. ℥iii

M. Sig. Teaspoonful in water three times a day.

Ptyalism.—For tender, bleeding gums from any cause, associated with fetid breath:

℞ Formaldehyde (40 per cent. sol.).....5i
Thymoli .....gr. x
Tincturæ benzoini compositæ.....5ii
Alcohol .....q.s. ad. ℥iii

M. Sig. Teaspoonful in wineglass of water as a mouth wash every two or three hours.

Trigeminal Neuralgia.—During the acute attack it is often the best policy to resort at once to the hypodermatic use of morphine, which will not only still the pain and bring the patient quick relief, but, as some authors claim, it may even have a curative effect. The danger of establishing the morphine habit renders a trial of other analgesics preferable in all but the most severe attacks. Quinine in ten grain doses, repeated once or twice, should be given when there is the least suspicion that malaria may be the underlying cause. Salicylate of soda stands only second to quinine with which it may be given and by combining with them one of the coaltar derivation a most effective anti-neuralgic preparation is obtained. The dangers attending the administration of the last mentioned class of remedies should never escape the physician's memory. Gelsemium in doses of five to fifteen drops of the tincture is a powerful remedy that is less used now than formerly. Iodide of potassium in full doses is often beneficial even in patients in whom no suspicion of syphilis exists. Arsenic in the form of Fowler's solution is one of the most reliable remedies. Counter irritation of any kind may bring relief. An elegant preparation will be obtained by mixing in equal parts chloral hydrate, camphor and menthol. On sensitive faces this may cause a blister. Heat or electricity is useful and should not be forgotten when running the therapeutic gamut in search of the the remedy for the individual. In selecting the effectual treatment for each patient there is opportunity for the exercise of much skill on the part of the physician in testing the several lines of treatment in rapid succession. Should all fail the intervention of surgery must be sought.

For Headache of Ovarian Origin.—

℞ Ammonii bromidi 5vi
Ext. hydrastis fl. .....℥ss
Tinct. gentian. comp. .....℥iss
Aquae .....℥iv

M. Sig. A dessert-spoonful three times a day.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 8, 1905.

ONE ASPECT OF THE TUBERCULOSIS QUESTION.

Tuberculosis will never be conquered until the public intelligence grasps the situation and the public will is directed to grappling with it. Consequently it is gratifying to note the educational trend of present efforts as exemplified in the deliberations of the Society for the Study and Prevention of Tuberculosis.

How most surely and swiftly to accomplish this educational end is the practical side of the question. No education will be received which does not arouse a personal and active interest, and to arouse such an interest in the public at large it is necessary to appeal to an absolutely universal motive.

All are not born altruists, but some achieve altruism and some may have altruism thrust upon them. Some will join in the antituberculosis campaign from sheer philanthropy; some by personal experience or that of their friends have come to recognize the needs of others; but there remains a large proportion of the frankly self-centered who can be made to realize the situation only by pointing out to them the economic value as such, by charging it up to profit and loss. Those who listen unmoved to the horrors of the White Plague among the tenement population, because of their very remoteness, are arrested by the fact that each death from tuberculosis entails an economic loss to the community of from $1,500 to $2,000. What does this imply to the city of New York alone? By conservative estimate an annual loss of productive labor amounting to over $20,000,000. The same calculations as applied to the whole country give a total annual loss of $330,000,000. Surely in view of these figures it is not unreasonable to demand the same sum to be applied to prophylactic measures which shall ultimately eliminate the needless loss.

Such are the arguments which must be presented in order to bring about a popular cooperation between the ideals of the altruist and the investments of the commercialist.

It should be the function of every practising physician to foster and further this point of view, and when the public shall have accepted it with its implication of utilizing national resources as an ounce of prevention rather than as a pound of cure, then and not till then, as Mr. Devine justly points out, the ultimate responsibility devolves again upon the medical profession.

Let no one think that the success of the economic appeal implies a purely sordid and commercial spirit. Such success is achieved only through a growing sense of essential unity in the social body, a sense pregnant with hopeful possibilities.

THE PROPHYLAXIS OF SCARLATINAL NEPHRITIS.

It is twenty years since Jaccaud recommended an absolute milk-diet in scarlet fever, as an efficient precaution against nephritis, and this practice has been universally followed. But, recently, doubt has arisen in the minds of many clinicians as to the wisdom of this procedure. The experience of one careful observer may serve to put these doubts to rest.

The observations of San.-R. Dr. Ziegler (*Centralblatt f. Kinderheilk.*, May, 1905), represent his experience in the treatment of 218 cases of scarlatina, both in private practice and in the Hospital for the Orphans of Military Men in Potsdam, his observations extending over a period of fifteen years. During the first half of this period there were 115 cases which did not receive the prophylactic milk-diet. Of these cases fully 50 per cent. developed nephritis, of which five died. In the remaining half of this period, in the 103 cases of scarlet fever, 100 received a milk-diet, with not a single case of nephritis. Of the remaining three cases which

did not receive a milk-diet, two developed nephritis.

Statistics have sometimes been characterized as exceedingly untrustworthy, particularly in medicine. The above figures, however, are a convincing argument in favor of the prophylactic treatment of scarlatinal nephritis.

In spite of these and similar experiences, many modern clinicians still look with dubious eyes upon the efficiency of the milk-diet in scarlatina. Of these Baginsky favors milk-diet for only the first fourteen days of the disease, and believes that even then the possibility of the appearance of nephritis cannot be avoided.

Another observer, Zuppinger, of Vienna, utterly discredits any preventive value of the milk-diet in scarlet fever, and of the same belief are Piza (Hamburg) and Fischl, in Biedert's Text-Book of Children's Diseases, who, moreover, attribute to the milk-diet a positive harm to the patient, by diminishing his nutrition.

If the earlier experiences of Ziegler may be cited as an argument in favor of the milk-diet, then his results since 1892 may be considered an adequate refutation to the argument of the above. During this time he treated 138 cases of scarlet fever, of which 131 received the milk-diet. Of these 130 remained free from nephritis, while one case suffered from nephritis after a complicating attack of diphtheria. The other six cases entered the hospital during the stage of desquamation, with nephritis in full blast, while one contracted it owing to disobedience of orders in partaking of a mixed diet with other patients. In these seven cases, therefore, the prophylactic milk-diet was not employed.

All these cases reported comprised 13 hospital epidemics and 24 isolated cases, and represented forms of scarlet fever of practically the same type and virulence. The results of Ziegler, therefore, furnish a nice scientific demonstration of the value of this dietetic procedure, which may be placed in the same category, as regards convincing completeness, with the statistics of the antitoxin treatment of diphtheria.

SOME COMPARISONS.

Nothing is more salutary and illuminating than an occasional unprejudiced comparison of our own standards with those of others. An opportunity for such a comparison is offered the American medical profession in the statistics and comments set forth in the *British Medical Journal* for June 3, already referred to editorially in our issue of June 17, 1905. These statistics include summaries of the educational and legal requirements for the practice of medicine in 19 foreign countries and colonies.

Viewed as a whole the uniformity of these standards is more noticeable than the deviations. In certain items the requirements of foreign countries are practically unanimous among themselves but different from those in America, particularly in the length of time required to be spent in medical study, which covers a period of from five to seven years. The entire cost of tuition, also, strikes the American mind as temptingly low. In France, for instance, the total necessary cost of a professional education is estimated at something less than $300. A preliminary general education is a universal requirement abroad, ranging from a liberal high-school course, as in Holland, to one terminating in the degree of B.A., as prescribed in Denmark. In many instances a generous allotment of the classics is specifically indicated. It is possible that in certain cases these preliminary requirements are more imposing upon paper than in actuality. Spain, for instance, prescribes the equivalent of "the degree of bachelor," but the fact that the course is usually covered "between the ages of nine and fifteen years" indicates its secondary character. For the most part, however, the statements undoubtedly represent solid and actual attainments. At the lowest, this contrasts with the general condition in this country, where so many of the medical institutions practically waive preliminary education.

The medical course once embarked upon differs very slightly from that in our own country, comprising courses in physics, chemistry, histology, anatomy, pathology, materia medica, general medicine, surgery, obstetrics and the special branches. The curricula of the various countries differ chiefly in point of emphasis. Thus in Germany stress is laid upon personal clinical instruction, whereas in Italy the method is largely one of demonstration, allowing a wider field for experimentation and research, but failing to provide, as the clinical system does, the personal contact with actualities and the precision consequent thereon.

It is interesting to note how the twofold aspect of the profession, academic and social, which is indicated in this country by the double requirement of diploma and license, is recognized abroad. In France and Italy the State license carries with it the title of Doctor of Medicine. In Austria,

Hungary, Denmark, Belgium and Spain, the degree carries with it the State license. In the latter four countries, however, the university practically is a department of the State. In Germany the two phases are kept distinct, the *Staats-Examen* giving the right of practice, but not conferring the degree, a function reserved to the university. The degree is said to be taken, however, by nearly all practising physicians in Germany. In Holland, where a similar separation obtains, the difficulties in the way of getting a doctor's degree as regards preliminary education and academic training make the majority content with the degree of *Arts*, which confers the privilege of practising.

An interesting corollary to the matters noted is to be found in the notes on the social conditions existing in the various countries. Oddly enough the extremes in this respect are both found in Latin countries, the lowest in Italy where the profession is recruited from those of plebeian birth to whom the doors of "society" are forever closed except in instances of phenomenal eminence, and the highest in Portugal where doctors are "at the top of the social ladder." In Hungary a doctor wins little recognition, and in Austria his standing is only fairly good. In the Netherlands, however, a certain prestige attaches to the profession, and in Denmark doctors are regarded with the same respect which is accorded to the minister and the judge.

In most European countries there is a suggestion of caste foreign to American ideas, but in other respects the privileges, duties and problems of the profession are much the same as we find them here.

ECHOES AND NEWS.

NEW YORK.

$17,000 to Kill Mosquitoes.—The Appropriation of $17,000 for the mosquito warfare which Health Commissioner Darlington proposes to conduct on Staten Island, has been granted by the Board of Estimate.

New Emergency Hospital.—St. Gregory's, a new emergency hospital has been opened in the four-story building at 93 Gold Street. It will take the overflow from the busy House of Relief in Hudson Street. Superintendent Flater, Assistant Superintendent Duncan, three ambulance surgeons and four nurses make up St. Gregory's staff. The hospital has also two visiting surgeons.

Brownsville's Hospital.—Young women and young men of Brownsville have formed a society called the Mount Carmel Benevolent Association. The object of the society is the building of a hospital, in some select place of Brownsville, for the benefit of the poor. The hospital will be named the Mount Carmel. The society has about two hundred members, and donations were received last night amounting to $1,200, including dues.

No Site Chosen for the City's New Tuberculosis Sanatarium.—Dr. Darlington, president of the Board of Health denies the report that he had secured a site in the towns of Greeneville and Mount Hope, for the new tuberculosis sanitarium. He said he had looked over a number of sites, and had secured options on some. He has the consent for two locasions near the Hudson River, forty miles from New York, and thought it probable that he would take one of these.

City in Good Health.—The death-rate in this city for the first six months of this year was considerably lower than for the corresponding period of 1904. It was nearly as low as the death-rate in 1903, and but for cerebrospinal meningitis would have been the lowest death-rate for several years. The death-rate for the past six months was 19.75; for 1904, 22.68 and for 1903, 19.14. For the week ending on Saturday last the death-rate was 18.55 as compared with 21.63 for the same week in 1904.

Ambulance Surgeon Injured.—Dr. T. Harris Cherry, a surgeon in Hudson Street Hospital, was injured, perhaps fatally, and his driver, Edward Stokes, was hurt, when an ambulance in which they were answering a call for a Fourth-of-July accident was struck by a northbound Sixth avenue trolley car at Centre and Reade streets, on July 4. As a result Dr. Cherry is suffering from posible fracture of the skull, scalp wounds, five broken ribs and internal injuries. He was taken back to the hospital, where his condition is extremely serious, particularly because of his internal injuries. He is a native of Georgia and a graduate of the College of Physicians and Surgeons of this city. He has been at Hudson Street Hospital about a year.

PHILADELPHIA.

Infected During an Operation.—While performing an operation some time ago Dr. Francis R. Packard infected one of his fingers and as a result he is now ill at the Pennsylvania Hospital; his condition is improving and recovery is expected.

To Study Foreign Methods of Nursing.—Miss Georgie R. Weaver, directress of the Philadelphia Lying-in Charity Hospital, and Miss Edith A. McPherson directress of the Nurses Training School of the Medico-Chirurgical Hospital, sailed for Europe last week. They will visit various hospitals in Germany, France and England to study the methods of nursing.

Free Bed Endowed.—P. F. Kernan has endowed a free bed in St. Mary's Hospital, in memory of Harriet Richards, of this city, who died last year. Mr. Kernan has stipulated that the bed shall be used by any worthy person without regard to color, race or religion. It will be under the patronage of the Sisters of St. Francis attached to St. John's Catholic Church.

Meeting of the Dental Association.—After many papers pertaining to dentistry were read, the society elected Dr. H. W. Arthur, of Pittsburg, president; Dr. J. T. Lippincott, of Philadelphia, first vice-president; Dr. L. N. Weaver, of Philadelphia, recording secretary; Dr. V. S. Jones, of Bethlehem, corresponding secretary; Dr. R. H. D. Swing, of Philadelphia, treasurer. Dr. W. J. Roe gave a clinic at the Jefferson Hospital upon two case of cleft palate. The Medico-Chirurgical Hospital gave luncheon to the members of the society.

To Keep in Touch with Hospital Reports.—Auditor-General Snyder has instructed the traveling auditors of Pennsylvania to examine every three months the books of all the hospitals receiving State aid, and report to him the number of free patients, the number of pay patients, and the amount paid weekly by the latter. This information will be sent to the legislature to be used in regulating the amount of appropriations given to each hospital. This procedure will prevent padding hospital reports when appropriations are wanted.

CHICAGO.

Decrease in Contagious Diseases.—With the exception of smallpox, all the other contagious and infectious diseases show a decrease in the number of cases reported.

Opening Exercises of the Chicago Emergency Hospital.—This hospital was opened Tuesday, June 27, at 309 Fifth Avenue. Dr. Richard M. Fletcher is surgeon-in-chief.

Graduation Exercises of Jenner Medical College.—The Jenner Medical College also held its graduation exercises this week, when 15 degrees were given. The address was delivered by Dr. Stuart Johnstone. The class valedictorian was Dr. John D. McKellar.

Hospital Population.—The hospital population of Chicago is lower than at any time since last November, numbering 1,798. The only disquieting feature in the state of the public health is an increase of the typhoid fever contingent, which is unusual at this time of year, and is due, probably, to the quality of the water supply during the past two months.

Commencement Exercises of Dearborn Medical College.—The college held its commencement exercises this week, when 29 students received degrees. James H. Eckels was the principal speaker. He referred to the great responsibilities which rest on physicians, and emphasized the importance of long and careful preparation needed for that profession.

Chicago Casualties.—Returns to the *Record-Herald* up to eleven o'clock P.M., covering Fourth-of-July fatalities, accidents and fires show that twenty-one are dead and 536 injured on account of the celebration. Like figures a years ago up to two o'clock in the morning showed forty-eight fatalities and 1,545 injured. Casualties this year show the following causes: Runaways, 11; toy pistols, 28; powder burns, 70; firearms of all kinds, 94; fireworks, 298; cannon, 35.

Smallpox.—More cases of smallpox have been discovered in this city since the first of the year than during the whole of the previous year. The health department, suspecting that laxity in vaccination is the cause of the increase, have planned to renew a campaign of education. Vaccination of children at an early age is deemed advisable, in view of the fact that most of the cases recently reported have been among the younger children.

Chicago Medical Society Seeks to Enjoin Park Board.—Injunction proceedings have been begun by the Chicago Medical Society to restrain the south park commissioners from interfering with the erection of a monument to Samuel Guthrie in Grant Park, at the foot of Jackson Boulevard. The officers of the medical society assert that it is their right, under ordinances passed by the park board and the city council, to carry out their monument plans. It is believed the park board will make vigorous opposition to the suit brought by the society.

Michael Reese Hospital.—The corner-stone of the new Michael Reese Hospital was laid last Tuesday, July 4, at 10 A.M., by Herman F. Hahn, Chairman of the Hospital Committee. Governor Deneen was present as the guest of honor, and delivered an address. The new hospital, costing $500,000, will be completed next May, and will be six stories in height, of solid masonry, steel and tile, and equipped with the most approved system of heating, lighting and ventilation. There will be accommodations for 240 beds, including sixty private rooms. There will be three operating rooms, and special provisions for isolating patients in the surgical, medical, gynecological and maternity departments. The children's building for both pay and charity patients will be separate from the main buildings, and will have an entrance from the outside.

GENERAL.

No More Plague in Panama.—The indications now are that the danger of the spread of bubonic plague has passed, owing to the energetic and prompt measures of the United States health officials. There has been only one case of the disease, that which occurred at La Boca, and since that was reported the period of incubation has passed without any new case developing. The infected La Boca wharf and village are now thoroughly cleaned and fumigated. If there are no new cases within a fortnight it is the intention to declare La Boca free of plague. In the meantime vessels are being discharged and loaded in Panama Bay. La Boca is entirely isolated.

Foreign Food Products.—Dr. Harvey W. Wiley, chief of the Bureau of Chemistry, is on his way to Europe under instructions from Secretary Wilson, to make an exhaustive investigation of methods of preparing and preserving food products for shipment to America. He will visit all of the leading cities of Europe which have an export food trade with the United States and will be gone until the middle of September. The policy is to have a more rigid inspection of foods. Upon his return laboratories will be established in Boston, Philadelphia, New Orleans and Chicago. At present the only inspection laboratories are in New York, San Francisco and Washington.

Control of the Tsetse-Fly Peril.—The Cologne *Gazette* prints extracts from private letters written by Prof. Robert Koch, who went to German East Africa at the end of 1904 for the further investigation of certain tropical diseases, showing that he had already made important discoveries in connection with the tsetse fly. The Professor found the breeding ground of the fly, and says that the fly can be rendered harmless through simple means. It will be remembered that Professor Koch made the still more important discovery that trypanosoma microbes, which are present in sleeping dropsy, exist in the tsetse fly. He further discovered in April last that the relapsing fever is transferred to man through a small sand tick.

Yellow Fever Situation.—The Panama Canal Commission has received a report by cable from Gov. Magoon relative to the yellow fever situation in June. Only two deaths occurred among employees appointed by the United States and two from among employees of the commission appointed to the Isthmus. The official records show that on June 1 there were employed on the Isthmus 1,493 Americans and 8,209 persons appointed on the Isthmus. On June 27 Gov. Magoon reported the death of S. J. Hirsch, an American clerk in the employ of the Canal Commission. Giovanni Janicelli, non-employee, died on July 1 of yellow fever. No additional cases were reported on that day.

Mosquito Reduction in California.—The California State Board of Health, in its monthly leaflet for April, 1905, calls attention to the utility of a crusade against mosquitoes in certain parts of the State for the purpose of minimizing malarial infection. Last year the marshes about San Rafael were inspected by representatives of the entomological department of the University of California, and those found infested with mosquitoes were treated with crude oil, giving the most satisfactory results, until late in the year, when lack of funds caused a suspension of work and a consequent increase of mosquitoes. A large marsh area, extending from South San Francisco nearly to San Mateo, is the seat of operations this year. Fresh water areas, which abound in the region under treatment, are either filled up with earth, drained, or treated with oil.

Boston Floating Hospital.—The Boston Floating Hospital will commence its trips down the harbor July 6, continuing until late in September. This excellent charity was founded in 1894 by Rufus Tobey, who has given his services to it since that date. A large sum of money is on hand and more is being collected for a new and larger boat, but for this season the present one is being overhauled. The new hospital will, it is hoped, accommodate 100 patients and be provided with a permanent contagious ward. The only requirement for admission is the signature of a physician on a properly filled out certificate; these certificates are in the hands of all the hosiptals and many physicians. The patients must be under six years of age; provisions are made for mothers and one other child during the day.

State Board of Health Guards Against Tetanus.—The June bulletin of the State Department of Health of Massachusetts called special attention to the fact that tetanus frequently follows Fourth of July and other injuries, especially where dirt, paper cartrige wads and other foreign substances are carried into the wounds. It urged all physicians who treat persons injured in this way to administer preventive does of tetanus antitoxin at the time the wounds are dressed. This procedure will surely prevent lockjaw. The department believes that many cases of this disease were prevented last year by this means, but says that there is no reason why every case could not be prevented. Generous supplies of the antitoxin produced in the department's antitoxin laboratory were sent to local health officers of all the large cities and villages and many towns, and the bulletin urged such officers to spread broadcast the information that any physician can obtain gratis what he needs by applying to the health officer.

India and Applied Chemistry.—At the Sixth International Congress of Applied Chemistry, which is to be held in the spring of 1906, at Rome, India, and its work in this direction will be officially represented for the first time. The committee in charge of matters consists of Major C. H. Bedford, D.Sc., M.D., of the Indian Medical Service, Chemist to the Imperial Government of India, as president, and of eight members, all of whom are either Professors of Chemistry at the Indian Universities or chemists to one or other of the provincial governments. There is room for a great deal of original work in India in various branches of applied chemistry, and of late years much activity has been shown. In particular the physiological action and chemical nature of various by-products found in different kinds of native spirits is being investigated at the County Liquors' Laboratory, at Kasauli, of which Major Bedford is director, the object being to enable the government of India to prescribe standards and tests of quality for the different forms of alcoholic liquor locally prepared.

Typhoid Due to Milkman.—A number of cases of typhoid fever are reported in Lynn, Mass. Although the health board of that city has received returns of only one case during the past month, the fact remains that the situation is of such a nature as to cause some anxiety among the physicians. One physician has six cases at present, and others have a lesser number, and the fact that the Lynn health board records show but one case is due to the failure of physicians to report the cases, as they are required to do by law.

Dr. Frank L. Morse, inspector of the State Board of Health, visited Lynn recently to look into Lynn's water supply. He is said to have expressed some uneasiness over the low condition in which be found the storage basins. Dr. Morse discovered that a boy who was employed by a milkman was taken ill with typhoid fever. The boy assisted in bottling and delivering the milk. He worked several days before it was discovered that he was afflicted with typhoid fever. Dr. Morse believes that this boy was the original cause of at least seven cases of typhoid fever. About ten days ago the milkman was taken ill with typhoid fever.

To Reform Hot Springs, Ark.—Hot Springs, Ark., sometimes called the Monte Carlo of the Southwest, will no longer be a haven for the sporting element of the country, if Mr. Hitchcock, the Secretary of the Interior, can prevent it. The Hot Springs reservation is under the jurisdiction of the Government, and Secretary Hitchcock is the responsible officer. He has received many complaints from Government agents recently to the effect that Hot Springs is coming to be looked upon rather as a gambling than as a health resort. Secretary Hitchcock intends to preserve the utility of the reservation as a health resort if possible, but he is at loss as to how to proceed. The gambling resorts and questionable houses are off the reservation proper, and Government authority is accordingly limited. It is believed, however, that by amending the regulations governing the use of the springs the moral tone of the place can be bettered. Failing in this, Secretary Hitchcock will take another tack. Politics is said to be responsible for the fact that Hot Springs is a wide-open town. Complaint is made by reputable citizens there that efforts to reform are frustrated by the politicians. If the Secretary of the Interior finds that he is powerless to reach the lawless element he will call the attention of the Attorney-General to the conditions, with a request that he endeavor to bring about the enforcement of the laws by the local authorities.

The Disease Problem on the Isthmus.—The troubles in the Panama situation are apparently increasing daily. The resignation of Chief Engineer Wallace at a time when his own plans for organization are left in a confused and incomplete state and when so much depends on centralized and authoritative control of a complicated system of work is followed by the news of yellow fever cases increasing in number and also the appearance of bubonic plague on the Isthmus. While there may be no occasion for serious alarm as to the immediate spread of either disease, their existence in any shape cannot fail to have a depressing effect on the workmen already on the ground and will inevitably demoralize others who may contemplate joining the force. The fear of the disease has spread to other ports in the neighborhood, and a declaration of quarantine against the canal belt will by no means tend to quiet public opinion regarding the present situation of affairs. It is quite evident that the sanitary problem is the one of first importance. The most strenuous efforts of the chief medical officer at Panama should be directed toward stamping out both pests with the least

possible delay. If he has been hitherto hampered in any way he should be given the freest rein for the exercise of his authority. In no other way can the present difficulties be properly met. In the present state of sanitary science and when the well understood preventive measures are properly applied there is no longer any reason why yellow fever or plague should exist anywhere, especially in such districts as are under the control of the United States government.

American Climatological Association.—At the recent annual meeting of this association Dr. E. L. Shurley, of Detroit, was chosen president and Dr. Guy Hinsdale, of Hot Springs, Va., secretary. The next meeting will occur at Atlantic City, May, 1906.

International Surgical Society.—The first congress of the International Surgical Society will be held in Brussels from September 18 to 23, 1905, under the presidency of Professor Theodor Kocher, of Berne. The following is the program of subjects proposed for discussion: (1) "The Value of the Examination of the Blood in Surgery," to be opened by Dr. W. W. Keen, of Philadelphia; Professor Sonnenburg, of Berlin; Dr. Ortiz de la Torre, of Madrid, and Dr. Depage, of Brussels. (2) "The Treatment of Prostatic Hypertrophy," to be introduced by Mr. Reginald Harrison, of London; Professor Rovsing, of Copenhagen, and Professor von Rydygier, of Lemberg. (3) "Surgical Intervention in Non-Cancerous Diseases of the Stomach," to be introduced by Mr. Mayo Robson, of London; Professor von Eiselsberg, of Vienna; Dr. Mattoli, of Ascoli Piceno; Professor Monprofit, of Angers; Professor Rotgans, of Amsterdam, and Professor Jonnesco, of Bucharest. (4) "Treatment of Articular Tuberculosis, to be introduced by Professor Bier, of Bonn; Dr. Broca, of Paris; Dr. Bradford, of Boston; Professor Codivilla, of Bologna, and Professor Willems, of Ghent. (5) "The Treatment of Peritonitis," to be introduced by Professor Lennander, of Upsala; Professor Friedrich, of Greifswald; M. Lejars, of Paris; Dr. McCosh, of New York; Professor Krogius, of Helsingfors, and Dr. de Isla, of Madrid. (6) "The Diagnosis of Surgical Diseases of the Kidney," to be introduced by M. Albarrán, of Paris; Dr. Kümmel, of Hamburg; Dr. Giordano, of Venice, and Dr. Lambotte, of Brussels. Other communications of a practical character, including the presentation of patients, specimens, and instruments, may be made. The conditions of membership of the Society, and further information relating to the arrangements for the forthcoming congress, can be obtained from the Secretary-General, Dr. Depage, 75 Avenue Louise, Brussels, or from Mr. Reginald Harrison, London, delegate for Great Britain.

Cancer Research.—Sir William Church, president of the Royal College of Physicians, addressed the third annual meeting of the cancer research committee, July 5. He said that the year's investigations confirmed the conclusions announced in 1904, that cancer is not associated with peculiarities of diet, climate or mode of life. The experiments had yielded the most interesting results, including a demonstration of the possibility of perpetuating malignant new growths through successive generations of mice in such a way that the cancer cells appeared to be gifted with the power of perpetual multiplication. This power, however, was not manifested at all times and under all conditions. The results thus obtained point to the necessity for more closely studying the processes of cell multiplication, for in this abnormal proliferation and reproduction appear to lie the malignancy of cancer and a clue to the solution of its mystery. This property of perpetual multiplication definitely separated cancer from known infective diseases. Much experimental work had been done in treating malignant growths, but immunizing with serums did not justify the claims sometimes made for them, although in some cases they deprived the cells of the power of growth. The action of radium and radioactive solutions had been carefully studied. It was undoubtable that these sometimes influenced the growth and development of normal and tumor tissues, but there was no evidence yet obtained that radium emanations had any selective or special action on tumor tissues, while the amount of radio-active solutions necessary to produce any action on the tissues far exceeded the quantity that could be safely introduced into the body.

New Jersey Licentiates.—At a meeting of the State Board of Medical Examiners of New Jersey, held at Long Branch, July 5, the following candidates, who passed the State examination at Trenton, June 20-21, were duly licensed to practice medicine and surgery in New Jersey: Herman Bryden Allyn, Philadelphia; Pasquale Bellino, Newark; Albert Page Berg, Philadelphia; Joseph Albert Biello, Philadelphia; Theophilus Henry Boyesen, Egg Harbor City; James Breslin, Freehold; Frederick Norman Bunnell, Tom's River; Ralph Robert Charlesworth, Millville; Arthur Harley Coward, New Egypt; William Price Davis, Jr., Atlantic City; Samuel Ward Dodd, Newark; Joscelyn Joseph Emmens, Philadelphia; Arthur Edward Ewens, Atlantic City; John Eugene Fahy, Philadelphia; Abraham P. Fishman, Providence, R. I.; Collin Foulkrod, Philadelphia; Frank William George, Princeton, Mass.; Frederick Snyder Hammond, Wilmington, Del.; Ernest Rutherford Hoffman, Collingswood; Albert F. Jackson, Campgaw; Charles Higbee Jackson, Camden; Claude Perry Jones, Somerville, Mass.; Henry Benjamin Kessler, Newark; Ignaz Klein, Newark; George J. P. Koch, Paterson; Thomas Benjamin Lee, Camden; Chester Arthur Leigh, Burlington; Harry Elmer Lore, Cedarville; Margaret Mace, Anglesea; Richard Sanford Mallon, Paterson; Amos Jones Mander, Philadelphia; Harrison Stanford Martland, Newark; James Henry McCroskery, Union Hill; Joseph Searle McDede, South Orange; Joseph Zimmerman McDermott, Freehold; William Bernard McGlennon, Newark, Llewella Maria Merrow, Atlantic City; George Grant Mills, Philadelphia; Arthur Caradoc Morgan, Philadelphia; Samuel Alan Muta, Bridgeton; Daniel Jerome O'Brien, Deep River, Conn.; Thomas Aloysius O'Brien, Philadelphia; Clarence Rutherford O'Crowley, Newark; Jacob Lyon Rosenstein, Jersey City; Eugene Paul Schaefer, Newark; Julius Segal, Carmel; George Sigars Spence, Vineland; James Harris Underwood, Woodbury; Nelson Shelly Weinberger, Doylestown, Pa.; Edgar Lee West, Hamilton Square; Edward Clendenning White, Camden; Walter John Whitehouse, Jr., Pottsville, Pa.; Joseph J. G. Williams, Longport; William Walsh Wilson, New Brunswick; Alfred Woodhouse, Trenton. The following officers were elected: President, Dr. Edward Hill Baldwin, Newark; Secretary, Dr. E. L. B. Godfrey, Camden; Treasurer, Dr. Charles A. Groves, East Orange. The medical license of New Jersey will be indorsed by the following States: Maine, Vermont, Delaware, Virginia, Illinois, Michigan, Minnesota, Kansas, Colorado and others.

OBITUARY.

Dr. GEORGE J. A. AHERN, of No. 151 East Thirty-ninth Street, New York, former surgeon of St. Francis Hospital, died suddenly July 4, in that institution, from a

pulmonary hemorrhage. He was thirty-four years old. He leaves a widow and three married sisters residing in this city. He was a graduate of New York University Medical College and was formerly on the staff of physicians at the Manhattan Eye and Ear Hospital.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, June 10.

THE PREVENTION OF PHYSICAL DEGENERATION—CAUSES OF MENTAL DEFICIENCY—SIR FREDERICK TREVES ON HIMSELF AND SOME OTHER THINGS—RETIREMENT OF A MEDICAL M.P.

PROPHETS of the Cassandra type have for some time been giving us the cheerful assurance that the British race is doomed to decay and extinction unless something is done to prevent its further deterioration. To many the alleged deterioration is not perceptible in the race as a whole; it is admitted by all, however, that the conditions of life in the slums of our large cities tend to produce physical degeneracy in their denizens. It has been said that a trueborn Londonor of the fourth generation is unknown. This is an exaggeration, but it embodies a truth of far-reaching importance. The British race is as strong as ever when it has the chance of growing to its normal standard. The rural population is, however, drifting more and more to the towns where the unwholesome environment, combined with drink and debauchery, in a few years wreck the stalwart countryman's constitution and leave their ineffaceable marks on his offspring. Unless this process can be checked there is a real danger that the manhood of the nation may in time be sapped. The doctrine expressed in the formula "Back to the land" has therefore a physiological as well as an economic application In the meantime a strenuous effort is about to be made to concentrate the scattered forces making for physical regeneration in a National League for Physical Education and Improvement. A meeting is to be held on June 28 at the Mansion House under the presidency of the Lord Mayor—the official *præsidium et dulce decus* of British philanthropy—at which the birth of the new League will be formally proclaimed. Its objects are stated to be:

1. The stimulating of public interest in the various societies which make the improvement of the physical condition of the people their special care.

2. The bringing into close association and, if possible, the federation of such societies, so that they may have increased strength, financial and otherwise.

3. The encouragement of, and the advising of, societies which find it difficult to hold their own under present conditions.

4. Assistance toward the starting of organizations for the benefit of physical health and well-being wherever they do not already exist, as, for instance, in remote districts.

The League, in short, aims at spreading knowledge of the laws of health and organizing a crusade against the causes of degeneration. Among the members of the medical profession who have consented to become vice-presidents of the League are Sir William Broadbent, Sir Thomas Barlow, Sir Frederick Treves, Sir Samuel Wilks, Sir John Burdon-Sanderson, Mr. John Tweedy, President of the Royal College of Surgeons of England; Sir William Turner, Principal of the University of Edinburgh, and late President of the General Medical Council; Sir Lauder Brunton and Sir Victor Horsley. The League will have the blessing of nearly the whole bench of Bishops, the Moderators of the Church of Scotland and of the Free Church, the Chief Rabbi, and Mr. Bramwell Booth. The luminaries of the law are also conspicuous in the list of vice-presidents, while science is represented by such men as Sir Norman Lockyer, Sir William Higgins, Sir Archibald Geikie, Sir Michael Foster and Sir William Ramsey. The leading spirit in the movement is Sir Lauder Brunton, whose views on one aspect of the question of physical degeneration are therefore of special interest. Speaking at a meeting of the Christian Social Union the other day he began with the comforting statement that there is a great deal of masculine energy and indomitable courage and steadfastness of purpose left in the Anglo-Saxon race; "it is for us, he said, "to make the most of these qualities, so that we may take our place among the nations." After referring to the fact that a committee which lately inquired into the matter had concluded that physical deterioration is a bogey, he went on to say that whatever opinions might be held on that point, there could be only one opinion as to the existence of physical inadequacy. No one could go to any large town without noticing men, women and children who were not fitly equipped for the struggle for life, but who were in the abyss and needed help. How, he asked, could such help be given? In a large number of cases parents are ignorant of what to do for the health of their children rather than wilfully careless. "We must," said Sir Lauder Brunton, "impress upon parents that the health of their children is in their keeping. But though parents must be mainly responsible for the health of their children, school teachers must realize that in training the brain the child's body must not be overlooked, and that opportunities must be given for physical recreation and physical training." It is a noble ideal that the League sets before itself. In the better rearing of the child lies the secret of healthy development. But there is one factor in the problem which is either lost sight of or purposely disregarded by our hygienic reformers, and that is the poverty of the parents. From that spring dirt, starvation and disease; in that, too, is engendered the viper-brood of drink and vice which poison human life at its source. The teaching of the laws of health may do something to lessen physical deterioration, but the only remedy that will really go to the root of the evil is the extinction of poverty. And for that we shall have to wait till the millennium.

Closely connected with physical deterioration is mental deficiency. A Royal Commission on the Care of the Feeble-Minded is now taking evidence on the subject. Sir James Crichton Browne, who is Lord Chancellor's Visitor in Lunacy, who appeared before it the other day, said there was reason to believe that thirty per cent. of the population were still living in poverty and were ill-housed, ill-clothed, and underfed—conditions which favored mental degeneration. Mental defects had, however, a much more complex causation than tuberculosis, and sanitary improvements had not reduced the prevalence of mental defects to the extent they had reduced tuberculosis. A large amount of mental defect was due to insufficient and improper feeding in infancy and childhood. Natural nursing had gone out of fashion, and many of the condensed milks and proprietary foods were unsuitable and harmful. Babies fed on them might look plump, but they were pale and flabby, and often suffered from rickets. But he believed that the effects of alcohol in the production of mental defects had been exaggerated. He did not think it played any part in the causation of more than fifteen per cent. of cases of idiocy

and feeble-mindedness. He said that the late Professor Laycock, of Edinburgh University, used to divide idiots into two classes—poverty idiots and luxury idiots. In the case of the latter the causes of mental degeneracy were indolence and self-indulgence through many generations and inter-marrying. The persons thus afflicted were called by Professor Laycock "spoon-bill" idiots, and he used to point out that they were the type represented in "Punch" as aristocratic noodles. He could not say that there were more cases of feeble-mindedness in the upper than the lower class, though among the former there was more inter-marriage. Incidentally Sir James Crichton Browne stated that he did not know a single case in which an inebriate had benefited by a stay in a "home." In some of these retreats he believed drinking went on. Moreover, the idle, loafing life led in these institutions must have a demoralizing effect. In the present state of the law there were a great many weak-minded people, including many who wasted their means, who could not be interfered with unless they showed themselves to be socially dangerous. Sir James Crichton Browne suggested, in regard to weak-minded persons who had been brought up in special schools, that after their training there they should be sent, not to their own homes, but to some place where they could be kept under observation. Weak-minded persons, with criminal and vicious tendencies, might, on the recommendation of the medical officer who had watched the case, be detained in a criminal observation home. Sir James said he knew a medical officer of a gaol who declared that one-third of the prisoners there detained showed signs of mental weakness.

Since he retired from the arena and ceased to raise Olympic dust in the race for professional victory, Sir Frederick Treves has not been idle. When he is not exercising his skill on some favored person to whom the King delights to do good vicariously, he is being interviewed by newspapers or making speeches. To a representative of *Cassel's Saturday Journal* he not long ago explained that he had given up his profession for the simple reason that there was too much to do. He went on to say: "Performing big operations every morning makes existence rather trying. I got tired of my duties; they bored me to death: so, after six and twenty years of practice, I retired. Not that my labors were breaking me down. Nothing would, I think, do that. I have no nervous system, not having had need of one, and I have never had to keep to my bed." Asked to give an account of one of his busy days, the distinguished surgeon said: "I was invariably downstairs at five o'clock. I breakfasted at half-past seven, and almost without exception there was an operation at nine. Then, right up till one o'clock, there were patients to see. After that I went out, and, having lunched in my carriage, devoted the afternoon to consultations. When did I get home? At all hours. This, as I have said, was a sort of existence of which anybody was liable to grow tired." Asked further as to the essential qualities needed for success in surgical work, Sir Frederick said: "The principal feature of success is good health. A surgeon must be strong; otherwise his temper suffers, and his judgment becomes faulty. He must always be fit—in the pink of condition—which is one of the reasons why whenever I had any spare moments I employed myself in swimming, boating, fencing, cycling. The position of a surgeon is one of vast responsibility, requiring extraordinary attention to detail. Not to fail, you must, if you are a surgeon, be alert, keen, perpetually on the *qui vive*. At any moment you may receive a telegram summoning you to some distant town, and unless you are fit you cannot respond to the demands that are made upon you." Sir Frederick Treves concluded the interview by saying that in his retirement he never had a minute to spare. And in point of fact he figures in the newspapers almost as often as a leading politician or a popular actor. One day he is addressing a teetotal meeting; the next he is singing the triumphs of modern surgery at a meeting of ladies interested in the Hospital for Women; another day he is telling the world that the future of the healing art is in the hands of the Japanese. His latest appearance, as far as I have been able to follow his "quick change" performances, was at a meeting of the National Health Society, last week, when he said that in matters appertaining to health the educated classes knew too much for their comfort. They dreaded germs as their ancestors dreaded ghosts. In the nursery the rattle was sterilized daily, and everything boiled, except baby. All the older people were on some highly specialized diet. On the other hand, the lower orders knew too little. They thought people were porous—as porous as blotting paper. They were very interested in eruptive fevers, eagerly watched for the eruption to "come out," and talked of driving it inside again. They had an extraordinary belief in meat, especially when red, and in port wine, because it was blood-colored, and therefore blood-making. Speaking with special reference to the work of the National Health Society, Sir Frederick said it would be well to teach women the actual physical capacity of a child's stomach and the desirability of being clean. Education would go far to abolish preventable diseases, such as anæmia, the diseases of malnutrition, acquired deformities, ill-health in women—and it was his experience that drinking among women came from ill-health, not from ill-morals. Treves's style of oratory, it will be seen, is breezy as becomes one whose love of seafaring led him to study navigation and obtain a master marine's certificate. He has, however, a tendency not uncommon among orators, to overstatement of his case. In his denunciations of alcohol, of which something was said in a previous letter, he, in the words of Lord Beaconsfield, became "intoxicated with the exuberance of his own verbosity" to such a degree as to come perilously near to talking nonsense. He is a good speaker, but as was said by the Emperor Augustus, of another overstrenuous orator, *sufflaminandus est*.

Dr. Robert Farquharson, who has sat in the House of Commons as the representative of West Aberdeenshire for a quarter of a century, has just announced his intention of not seeking re-election to a new Parliament. The reason is that his health has been failing for some time past, and he no longer feels himself equal to the strain of parliamentary life. His retirement will deprive the House of one of its most justly popular and respected members, and the medical profession of a trusted representative. He has played a very useful, if not a very conspicuous, part as a legislator. It was he who piloted the Public Health Act of Scotland safely into port through the treacherous cross currents of party strife; it was said at the time that he was the only member of the House who thoroughly understood that unweildy measure in all the intricacies of its innumerable clauses. Dr. Farquharson who is still a year short of seventy is the chief of the great Highland clan whose name he bears. His cousin, Farquharson of Invercauld, used to be known as the Queen's landlord, because he was the owner of Balmoral, Queen Victoria's favorite residence in Scotland; his brother, Joseph Farquharson, is a distinguished painter, whose speciality is Highland scenery. Robert Farquharson graduated at the University of Edinburgh, and began his professional life as Assistant Surgeon in the Coldstream Guards. After

eleven years' service he became Medical Officer to Rugby, the great school associated with the name of Dr. Arnold. Later he was appointed to the staff at St. Mary's Hospital; he lectured on materia medica, on which he wrote a little book which once had a great vogue among students. Then, suddenly, on the death of a relative he blossomed out into a Scottish laird, owning some 17,000 acres of land in a beautiful part of Aberdeenshire. He is a very familiar figure in London Society, and "gives away" countless brides at fashionable weddings. His walrus-like moustaches made him a favorite subject for the caricaturists of *Punch*. He is a man who has troops of friends and, I should think, not a single enemy.

SOCIETY PROCEEDINGS.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.[1]

Eleventh Regular Meeting, held April 19, 1905.

The President, Edmund B. Wilson, in the Chair.

Members Present.—Adler, Auer, Calkins, Emerson, Gies, Hatcher, Jackson, Lee, Levene, Levin, Lusk, Meltzer, Morgan, Murlin, Richards, Salant, Sherman, Torrey, Wallace, Wilson, Wolf, Yatsu.

Members Elected.—Harlow Brooks, W. B. Cannon, A. J. Carlson, R. G. Harrison, A. P. Mathews, G. H. Parker, A. E. Taylor.

ABSTRACTS OF REPORTS OF ORIGINAL INVESTIGATIONS.

The Relation Between Normal and Abnormal Development of the Frog's Egg.—By T. H. Morgan. The method of development of the frog's egg may be changed by a number of external agents. If the eggs are revolved at the rate of 180 revolutions per minute; if they are put into salt-solutions of definite strengths; if they are subjected to a low or to a high temperature; if they are deprived of sufficient oxygen, or surrounded by carbon dioxide in solution; if they are placed on wet filter paper instead of developing under water—in any of these ways abnormal embryos result.

An examination of the effects of these external agents brings out two points of especial interest. First, that the effects are not gradual, *i.e.*, corresponding in degree to the increasing strength of the agent employed, but that no effects appear up to a certain point, and then suddenly the agent begins to act. Increasing the strength of the agents above this point may, for a small range, increase the effect, but this occurs within extraordinarily narrow limits compared with the lower range of non-action. The most plausible explanation of this mode of behavior in most of the cases is as follows: The agents act by coagulating certain parts of the egg, thereby preventing their further development. Other parts of the eggs that are made up of different colloids or of different concentration of colloids remain unaffected, and proceed to carry out their development as far as the presence of the injured region allows.

The second point was the one that the author spoke of especially. Despite the great diversity in the form of the abnormal embryos most of them may be reduced to modifications of the same type. For example, in many cases the dark cells of the upper hemisphere do not grow down over the lower hemisphere to produce there the embryo, but, remaining at the top of the egg, partially constrict off from the yolk cells at, or even above the equator of the egg. Out of these dark cells the abnormal embryo develops usually in the form of a ring. Sometimes one side only of the ring develops and a half embryo appears; sometimes only the anterior end of the ring develops and an anterior embryo appears (often more or less "open"), etc.

The author especially called attention to the fact that the abnormal embryo develops in the material of the upper hemisphere, while the normal embryo develops over the lower hemisphere. Two interpretations of the difference seem possible. Either the material is totipotent and an embryo may develop anywhere in the egg, appearing in the less injured regions or the material for normal and abnormal development is the same and becomes carried downward during the early stage of normal development from the upper into the lower hemisphere.

The author tested these alternatives in two ways. In the first place he removed, with a needle, the two anterior, or the two posterior, or even all four of the upper blastomeres at the eight-cell stage. The results showed that when the two upper anterior blastomeres are removed the head end of the embryo is defective; when the two upper posterior blastomeres are removed the posterior end sometimes shows defects. When all four of the upper blastomeres are removed no embryo develops, although the blastoporic rim may appear near the equator of the egg, the gastulation process may begin and the differentiation of the germ layers take place to a certain extent.

The author concluded from these results that some at least of the material that goes to form the embryo lies at first high up in the upper hemisphere of the egg. In the light of these conclusions it became necessary to examine once more the early development, especially the pregastrula stages; for, despite the fact that the frog has been a classical object of study with embryologists for over a hundred years, no one has suspected that the embryo-forming material lies in the upper hemisphere and is transported to the lower hemisphere *before* the lips of the blastopore have appeared.

Briefly, the author's examination showed that throughout the early period of segmentation the material of the hemisphere gets pushed far out to the sides of the egg. This is brought about largely by the development of the enormous segmentation cavity. During the later cleavage period the yolk cells of the lower hemisphere push upwards into the segmentation cavity, almost obliterating it. This upward movement of the cells in the interior is compensated for by the moving downward below the equator of the outer layers of the egg. In this way the embryo-forming material is carried into the lower hemisphere. Along its edge the lips of the blastopore develop. The dorsal, lateral and ventral lips roll over the yolk (or more accurately the yolk draws in beneath their advancing lips) and the dorsal organs of the embryo (the embryo in a narrower sense) appear over the lower, or yolk hemisphere of the egg.

Rejuvenescence in Protozoa.—By Gary N. Calkins. The process of conjugation in protozoa involves either temporary or permanent union of two individuals. During this union there is a fusion of

[1] Proceedings reported by the Secretary, William J. Gies, Ph.D., of New York. The authors of the reports have written the abstracts. The Secretary has made a few abbreviations and minor changes.

nuclear material from both organisms, resulting in the formation of new cleavage nuclei in each exconjugant. The process is directly comparable with fertilization of an egg by a spermatozoon and the biological significance of the phenomena involved is probably identical in all living things.

Since 1876 it has been generally assumed that one effect of conjugation is rejuvenescence or renewal of vitality in both of the exconjugants. This assumption has never been submitted to experimental proof. In his Paramœcium work, begun in 1901, the author almost had the proof but allowed the opportunity for obtaining it to slip through his fingers without realizing its importance at the time. The author's object in bringing this up at the present time is to announce that on the last day of February, 1905, he started a new series of experiments with Paramœcium consisting of three different lines at present in about the fortieth generation after conjugation, mainly for the purpose of completing his earlier work.

Another point of general biological importance will also be investigated. In his original experiments the author found strong evidence that the old view that both exconjugants are rejuvenated is erroneous. In 20 pairs which were cultivated after separating from conjugation, one individual of each pair invariably outlived the other, thus indicating an incipient fertilization like that in metazoa. This phenomenon will be given careful study in the experiments now under way.

Temperature and Muscle Fatigue.—By Frederic S. Lee. It has been pointed out previously by the author and others that the contraction process of the muscles of cold-blooded animals in the course of fatigue becomes greatly slowed, while those of warm-blooded animals show no such phenomenon. Lohmann has recently claimed that a cold-blooded muscle on being heated to a mammalian temperature shows a course of fatigue similar to that of mammalian muscle, and, on the other hand, that a warm-blooded muscle on being cooled fatigues like the muscles of cold-blooded animals at a similar temperature. From these supposed effects he concludes that in the matter of fatigue there is no real physiological difference between the two groups of muscle.

The author has investigated the question by very careful methods in a considerable variety of animals and has not been able to confirm Lohmann's conclusions. The muscles of the frog and the turtle show their characteristic method of fatigue whatever the temperature. The muscles of warm-blooded animals, on being cooled and then fatigued, show either no slowing of the contraction process or only a slight slowing. The latter seems to be most pronounced in the rodents, namely, the rabbit, the mouse, and the rat.

On Intra-Ureteral Pressure and its Relation to the Peristaltic Movements of the Ureter, with Demonstrations.—By Daniel R. Lucas (by invitation). By means of a cannula placed in the ureter, and retained without ligatures, and which did not materially interfere with the peristalsis of the ureter, the intra-ureteral pressure and its relation to the peristaltic movements of the ureter were ascertained.

In nine experiments on animals anesthetized with morphine and atropine, the pressure in the ureter arose only to a minute degree, the average being a negative pressure, more pronounced under the influence of diuretics. In five, in which chloroform was used, the pressure was always positive, the irritability and contractility of the ureter were noticeably diminished. In six, under ether, the ureter was noted to be irritable and contractile three hours after the anesthesia was commenced; the pressure was low. In four, in which ether followed the administration of chloroform, ether showed a stimulating effect on the peristalsis, running the pressure rapidly down. In three, in which morphine and atropine, chloroform and ether were successively tried during the same experiment, the specific effect of each, as above noted, was again observed. In an animal in which anesthesia was produced by decerebration, irritability and contractility of the ureter muscle were noted; the pressure was low, tending to negative on stimulating the ureter distal to the cannula. In one animal anesthetized with cocaine by the lumbar puncture method, the same results as with morphine were obtained. In two artificially constructed systems, which were demonstrated, phenomena analogous to those observed in the animals were produced and the causes indicated.

The experiments seem to justify the following deductions:

(1) A suction normally follows the peristaltic wave of the ureter; at the same time a force is exerted on the fluid in front of the wave.

(2) When the ureter is normally acting, the pressure in the pelvis of the kidney remains constantly negative, this condition obtaining through the anatomical arrangement of the pelvis, which prevents it from collapsing under negative pressure.

(3) Under the influence of chloroform, or conditions which retard muscular tone and activity, the pressure in the ureter becomes greater than that prevailing in the bladder.

(4) It seems obvious, then, that the ureter functions as an active agent in the formation of urine. Sollman has shown in his perfusion experiments on excised kidneys that the formation of urine is largely, though, of course, by no means, wholly a filtration process.

(5) Ether anesthesia does not cause a cessation of the peristaltic movements of the ureter, but because of its suppressing action on the urinary secretion, the curves were not recorded.

(6) The ureter remains rhythmically contractile when excised and placed in warm physiological salt solution, or for some time after the death of the animal, when left *in situ*. Therefore contractility is not dependent on pressure.

(7) An increased flow of urine calls forth a more efficient peristalsis, and therefore does not result in an increased pressure.

(8) The force of the peristaltic wave was seen to raise a column of water of considerable height.

(9) When sufficient force is exerted by the intrinsic pressure, to overcome the peristaltic contractions, the urine is forced back into the uriniferous tubules, and accurate communication is attained with the vascular supply of the kidney. Consequently, the blood pressure conditions can be accurately transmitted to a recording instrument. The question then arises, why use an oncometer to obtain records of blood pressure conditions in the kidney?

(10) May not the diuretic effect which is noted after administration of such drugs as mercury, for example, be attributed, in part, at least, to the increased peristalsis of the ureter, causing, as it does, an increased negative pressure, and, therefore, an increased filtration of urine?

Further Observations Upon the Phosphorized Fats in Extracts of the Kidney.—By Edward K. Dunham. (Presented by Phoebus A. Levene.) Last winter, at a meeting of the society, the author reported observations showing that extracts from dried kidneys, obtained with the Rosenfeld alcohol-chloroform method, contained from ⅓ to ⅔ of their weights of lecithins. In the *Arch. f. Exp. Path. u. Pharm.*, Vol. 52, p. 173, Rubow, of Copenhagen, reports similar results of more extended studies, printed in Danish some months earlier.

During the last few months the author has learned that it is not necessary to boil with absolute alcohol and extract with chloroform in order to obtain the large quantities of extract yielded by the Rosenfeld method. Repeated extraction of the fresh, undried organ with 85 per cent. alcohol at 45° C. will accomplish practically the same result. When making these extracts, it was found that, upon cooling, the alcoholic solutions yielded a precipitate from which a substance resembling the protagon of Liebreich could be obtained. It is to this substance that the author directs attention in this report. The yield is from about 0.14 per cent. to 0.20 per cent. of the fresh organ, or from about 0.6 per cent. to 1.0 per cent. of the dried kidney.

In order to obtain sufficient material for analysis, the author employed the method used by Cramer, *Journal of Physiology*, Vol. XXXI, in preparing protagon from the brain. The method employed was, in brief, as follows: The minced kidney, freed from obvious fat, was treated with 5 per cent. sodium sulfate solution at 85° to 90° C., twice, the filtrates discarded and the coagulum extracted, first with 95 per cent. and then repeatedly with 85 per cent. alcohol, at the boiling point, and the extracts filtered from the coagulum in a hot water funnel. The filtrates were cooled to from 0° to 5° C.; the precipitate was filtered out and purified by boiling with absolute alcohol, diluting the filtrate with water to make 85 per cent. alcohol, chilling, filtering, treating the precipitate repeatedly with cold ether to remove cholesterin, dissolving in hot chloroform, reprecipitating by chilling, filtering and expressing all possible traces of chloroform. The resulting product is a white, somewhat crystalline substance, freely soluble in warm 85 per cent. alcohol or chloroform, but reprecipitating upon cooling. It contains fatty acids, phosphorus, methyl, sulphur, and, upon cleavage with dilute sulphuric or hydrochloric acid, yields a reducing substance from which an osazone may be prepared.

For purposes of comparison a similar substance was prepared from beef brains by employing the same method.

Analyses of these products, two from different lots of beef kidneys and one from beef brain, were kindly made for the author by Dr. P. A. Levene, with the following percentage results:

	From Beef Kidney.		From Beef Brain.	Cramer's Figures for Protagon from Beef Brain.
	One Per Cent.	Two Per Cent.	Per Cent.	Per Cent.
C	65.61	65.55	65.76	66.25—66.42
H	11.00	11.09	10.66	10.82—11.07
N	3.17—3.15	3.24—3.26	2.51	2.29
P	2.06	2.19	0.97	1.04
S	0.82		1.33	0.71

The substance from the kidney contains distinctly more nitrogen and phosphorus than that from the brain, and that obtained by the author from the brain contained considerably more sulfur than that prepared by Cramer; the cleavage products, however, show that all of these substances belong in the same group. The nature of the glucoside which may be obtained from these substances can only be determined by using larger quantities than have as yet been obtained, and the author hopes to report results in this direction in the near future.

Comparative Physiological Action of Salts of Neodymium, Praeseodymium and Lanthanum.—By B. J. Dryfuss and C. G. L. Wolf. The experiments were undertaken to investigate the comparative physiological action of three elements which are of equal valency, and of approximately the same molecular weight, and whose chemical properties are closely related.

The experiments were carried out in vitro and on unicellular organisms, bacteria and infusoria, frogs, pigeons, rats and guinea-pigs. The solutions used were the chlorides, isotonic with 0.6 per cent. sodium chloride. In one case the propionate was used without any marked difference in the result being observed.

The chlorides coagulate egg and serum albumin, but neither the purified albumoses from Witte's peptone, nor peptone are precipitated.

Dilute solutions delay the growth of bacteria and eventually kill. The solutions are not very toxic to spores. Opalina, paramoecia and vorticellæ are killed quickly equivalent solutions of the chlorides acting in the following order of strength: Neodymium, præseodymium and lanthanum.

In frogs voluntary and involuntary muscle are quickly put out of action. This is particularly the case with perfused muscle. The solutions act in the same order as with unicellular organisms. Intravenous injection causes almost instant death, due to multiple embolism.

Attempted chronic poisoning was unsatisfactory. The solutions were introduced both subcutaneously and intraperitoneally. Some of the animals died with ill-defined symptoms. Others remained well, except for areas of induration at the seat of injection. Experiments with oral administration and on elimination will be conducted.

As all the solutions, owing to hydrolysis, are acid in reaction, the authors are inclined to attribute a large share of the acute effects to the acid present. The salts range themselves in their toxicity according to their molecular weights.

The Influence of Bile Upon Blood-Pressure.—By S. J. Meltzer and William Salant. There have not been very many studies regarding the influence of bile upon blood-pressure, and among these the statements are conflicting. Thus Traube, who was the first to study it upon the kymograph, states that the intravenous injection of bile salts causes a considerable fall of the blood-pressure, while Edmunds states in a recent report from Halliburton's laboratory that the effect is an insignificant one.

Nearly all of the investigators of this question within the last fifty years have employed bile salts in their experiments. The results of the authors' experiments were derived from intravenous injections of filtered ox bile into rabbits. Of the several reasons for employing bile and not its salts one should be mentioned: it is the belief of the authors that for biological phenomena we have as yet no right to assume that the sum of the known parts is equal to the whole.

In these experiments all degrees of effects have been observed from an insignificant one to a considerable and even a fatal fall of blood-pressure. But

these different degrees could be produced at will. Besides the quantity and the concentration of the bile it was found that the rate at which it is introduced into the circulation is the most effective factor in the result. A quantity of bile of a given concentration, which, when injected slowly, would cause only an insignificant depression, brought about a tremendous fall of the blood-pressure when injected rapidly. By injecting rapidly normal salt solution the fact has been established that neither the mechanical effect of the rapid injection nor the temperature of the injected fluid can have anything to do with the pronounced effect which is invariably produced by the rapid injections of bile. Although the rapidity of the injection was known to be a factor in the results produced by injections of other substances, it was never taken into consideration in the studies of the effects of bile. Thus, there are also conflicting statements regarding the immediate fatal effect of intravenous injections of bile. These contradictions find their satisfactory explanation in variations in the rate of injection employed in different experiments. Thus, a quantity of bile which, when injected slowly, would produce hardly any symptom, causes death within two minutes if injected rapidly.

As to the cause of the fall in pressure or of the fatal outcome it is generally assumed that it is due to the effect of the bile upon the heart, although opinions differ as to whether it is the heart muscle or the heart ganglia which present the points of attack. As to the manner of the injury Traube, Leyden and other investigators are of the opinion that it is caused by malnutrition of the heart due to the hemolytic effect of the bile. This is *a priori* improbable since the fall of the blood-pressure sets in immediately at the beginning of the injection and the return to normal begins as soon as the injection is stopped. The authors have, however, disproved this theory by direct experiment. On quickly injecting bile the blood-pressure fell rapidly, and the animal died in less than two minutes. The blood which was obtained immediately from the right ventricle did not show a trace of hemolysis.

Autopsies of rabbits killed rapidly in the above-mentioned manner showed in most cases nothing but dilated, flabby hearts. The failure of the heart can be caused either by the bile affecting anatomically the heart muscles or the ganglia, or by a functional process, by inhibiting the heart's action. It is known that bile produces structural changes in muscles and nerve fibers and nerve cells, but it is hardly conceivable that the structural changes could be induced so rapidly, and it is still less conceivable that structural restitution would occur with such rapidity as has been observed to take place in the return of the blood-pressure. It is, therefore, more probable that the bile exerts an inhibitory effect upon the heart.

In this connection the following experiments are of interest:

(1) The inhibitory effects of a stimulation of the peripheral end of the vagus not only did not diminish during an effective injection of bile, but in a few instances were distinctly improved.

(2) The inhibitory effect of the vagus was manifestly unimpaired shortly before the death of the animal when the blood-pressure was not more than a few millimeters of mercury and the heart beats were scarcely perceptible.

A Report of Feeding and Injection Experiments on Dogs after the Establishment of the Eck Fistula.—By P. B. Hawk. (Presented by A. N. Richards.) The fistulous opening between the portal vein and the inferior vena cava was made in six dogs by Dr. J. E. Sweet. Observations were made as to the behavior of the animals when fed on a diet of proteid food. One typical experiment may be summarized as follows: During eleven days on a mixed diet, there were no abnormal symptoms. On the four succeeding days beef meal and milk were fed, with the result that on the fourth day pronounced ataxia, loss of sight and hearing, complete anesthesia and catalepsy were observed, recovery occurring on the next day. After fasting for twenty-four hours, the animal was placed on a diet of fresh, lean beef. In five days a recurrence of the above symptoms was noted. The death of the animal occurred on the fifty-ninth day of the experiment—after the dog had undergone a loss of 42 per cent. of his weight. Autopsy showed a fistulous opening 2 c.m. in length and no collateral circulation. In other cases the symptoms described occurred only after the addition of Liebig's extract to the meat diet. The administration to normal dogs of sodium carbamate, either by mouth or by intravenous injection, gave rise to none of the symptoms observed by Pawlow and associates.

On Chemical Fertilization.—By Jacques Loeb (Presented by William J. Gies.) 1. In two previous publications the author mentioned the fact that by applying two different methods of treatment to the unfertilized egg of the sea urchin, this egg could be caused to develop in a way which resembled in all its essential features the development of the eggs fertilized with sperm. These two methods consisted first, in putting the eggs for about two hours in hypertonic sea water (the method used in the early experiments), and second, in exposing the eggs for from one to two minutes to sea water to which a certain amount of acetic acid or formic acid had been added. When the old method alone was used the eggs did not form a membrane, nor did the larvæ rise to the surface. When the acid treatment alone was used, the eggs formed a membrane, and after about six hours divided into from two to six cells, but then died. When the eggs were exposed to the acid for only a short time, *e.g.*, for three-quarters of a minute, not all the eggs formed a membrane when put back into normal sea water; and in this case only those divided into two or four cells and subsequently died within twenty hours, which had formed a membrane, while those eggs which had not been exposed long enough to the acid to form a membrane neither segmented nor died. If both methods of treatment were, however, combined, those eggs which had formed a membrane developed at about the same rate as the eggs fertilized with sperm. A certain percentage of these eggs rose to the surface of the water in the usual way, while the eggs which had not formed a membrane either did not develop at all, or developed in the somewhat abnormal and slow way characteristic of the treatment by hypertonic sea water alone.

The reader will notice that the eggs were submitted first for about two hours to the hypertonic sea water, and then exposed to the acid. When the order was reversed, and the eggs were exposed to the acid first and afterward to the hypertonic sea water for about two hours, most of them died without developing. This seemed rather strange in view of the fact that in the case of sperm fertilization the membrane formation is the first act in the series of events, while in the above-mentioned experiments it was the last. It occurred to the author that by shortening the time of exposure of the egg to the hypertonic sea water, he might also accomplish the last

postulate of a complete imitation of the process of fertilization by physicochemical means, namely, to get the order of events identical in both cases. This idea proved correct. It was found that when the unfertilized eggs were exposed for about one to two minutes to 50 c.c. of sea water to which about 3 c.c. N/10 acetic acid were added, the majority of the eggs formed the membrane characteristic of the entrance of a spermatozoon. If these eggs were afterwards exposed for from thirty to forty minutes to 100 c.c. of sea water to which 14 or 15 c.c. of a 2½N solution of NaCl were added, those of the eggs which had formed membranes developed into swimming larvæ that rose to the surface. The author has raised these larvæ and they develop into perfect plutei as fast as the larvæ of eggs fertilized with sperm.

It is very remarkable that when the order is reversed and the eggs are put first into the hypertonic sea water for about forty minutes, and then into the acidulated sea water for about one or two minutes, not a single larva is formed, and the eggs behave, on the whole, as if they had been exposed to the acid alone. If it is desired to put the eggs into the hypertonic sea water first and then expose them to the acid, it is necessary to expose them to the hypertonic sea water at least an hour and a half in order to obtain larvæ. On the other hand, if the eggs are treated with acid first and then exposed to the hypertonic sea water for from an hour and a half to two hours, most of the eggs die in the early stages of development.

It may also be mentioned in this connection that if eggs are fertilized with sperm first and then exposed to the hypertonic sea water of the above-mentioned concentration for about two hours, many more eggs die without reaching the larval stage than when the order is reversed. It is therefore obvious that the process of membrane formation caused by the spermatozoon modifies the sensitiveness of the egg to the hypertonic sea water in the same sense as the process of membrane formation caused by the acetic acid. If eggs are fertilized with sperm and then exposed to the hypertonic sea water for from about thirty to forty minutes, their development becomes almost identical with that of the unfertilized eggs treated first with acid and then exposed to the hypertonic sea water for the same period of time. The majority of these eggs segment and develop in a normal way.

2. The question arises as to how far the division of labor between the two agencies used in these experiments goes. Does the treatment with acid cause only the formation of the membrane, or does it also set the internal mechanism of nuclear and cell division into motion? And what is the rôle of the treatment with hypertonic sea water? From the author's earlier experiments he had expected that the latter was required to cause the internal changes necessary for karyokinesis. The direct observation, however, of the eggs treated in the above-mentioned way with acetic acid, shows that the acid treatment causes the formation not only of the membrane, but also, in due time, of the karyokinetic spindle, while the eggs exposed for only thirty or forty minutes to the hypertonic sea water do not show any karyokinetic changes, or, in fact, changes of any kind. It is a striking fact that the spindle formation which can be observed in the living egg of *Strongylocentrotus* seems to be identical in the cases of the fertilized egg and the unfertilized egg treated with acetic acid in the above-mentioned manner. The rôle which the subsequent treatment with the hypertonic sea water for from thirty to forty minutes seems to play is, in the first place, the acceleration of the process of segmentation. When the eggs are treated first with acid, and then for about thirty or forty minutes with hypertonic sea water, they begin to segment, at a temperature of about 19° C., in from an hour to an hour and ten minutes after they had been removed from the hypertonic sea water. After this they go on segmenting at the rate and usually in the manner characteristic of the fertilized egg. The eggs treated with the acetic acid alone, after having formed a membrane, do not begin to segment for about five or six hours (if they segment at all), and they do not develop beyond the four or eight-cell stage, dying as a rule within twenty hours. The treatment with hypertonic sea water, therefore, first accelerates the mechanism of cell division originated by the acid treatment, and second, indirectly through or in addition to this acceleration, increases the vitality or prolongs the life of the egg.

It is not yet possible to say how the acid brings about its effects. Several years ago the author ventured the suggestion that the process of membrane formation was due to coagulation. The author's recent experiments, however, contradict such an assertion, inasmuch as the membrane formation never occurs while the eggs are in the acidulated sea water of the above-mentioned concentration, but only after they are taken out and put back into normal sea water. If the process of membrane formation were due to coagulation by acid, it should occur while the eggs are in the acidulated sea water.

The author considers it possible (but far from proved) that the membrane formation by the spermatozoon and possibly the subsequent process of karyokinesis are due to the transitory action of an acid carried by the spermatozoon into the egg or produced transitorily by the spermatozoon in the egg; and that, in addition, the spermatozoon carries a second agency or substance into the egg which supplies some of the conditions produced in the above experiments by the brief treatment with the hypertonic sea water.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, held March 1, 1905.

The President, Arthur V. Meigs, M.D., in the Chair.

Gall-Stone Obstruction of the Bowel.—Dr. Alfred C. Wood reported a case of a woman, aged fifty-eight years, who was admitted to the University Hospital for obstruction of the bowel of five days' duration, pain in the abdomen and vomiting. This was preceded by diarrhea lasting one week. For three months prior to this the patient had alternating periods of constipation and diarrhea lasting three or four days. The only other illness having any possible connection with the case occurred eight months before her admission to the hospital. At this time the patient complained of pain in the chest, the attack being called pleurisy. All purgatives administered by the mouth were promptly vomited, and enemata were ineffectual. An operation was performed for the relief of the obstruction, and a gall-stone was found completely filling the lumen of the ileum about six inches from the ileocecal valve. This was removed by incising the bowel and the wound closed with Lembert sutures. As the stone was faceted at either end an examination was made to determine if any others remained in the body. When the hand was passed through the abdominal incision to the region of

the gall-bladder another calculus could be felt in a mass of adhesions. The first incision was then closed with sutures, and a second made over the region of the gall-bladder. In the center of a mass uniting the pylorus, liver, gall-bladder and ducts another stone was found and removed. This wound was drained with gauze. The patient made a good recovery, being able to leave the hospital six weeks after the operation. The wound had closed one week previously.

Dr. J. Allison Scott reported the removal of a gall-stone, 2 inches by 1 inch, from the duodenum, with a suppurative condition for 6 inches or 8 inches on either side in the case of a woman over sixty years of age. The bowel was resected and the woman died. He regards the intermittent attacks of pain as having important diagnostic significance. He has found in the literature reports of two cases of aged women whose gall-stones had been passed at the administration of half a pound of metallic mercury.

Dr. John B. Roberts referred to a case in which he had removed a large intestinal calculus 2½ inches long from a woman who had been suffering many years with the symptoms presented in Dr. Wood's case. There were evidences of old adhesions in the region of the liver, and the stone was covered with intestinal concretions. In the case of another patient a stone 1½ inches long was passed after an attack of severe pain.

The Gardner's Spade Deformity and the Silver Fork Deformity in Fractures of the Carpal End of the Radius.—Dr. John B. Roberts said that these lesions continue to be badly treated by a great number of practitioners, and that it seems impossible to convince the profession that restitution of the normal concavity of the palmar surface of the lower part of the radius is essential for comfortable convalescence and perfect cure. This must be accomplished, even if great force is required to disentangle the fragments and thrust the lower piece into its normal relation with the upper. The so-called "silver-fork deformity" of the fracture, with displacement of the carpal fragment backward, he said, must be absolutely overcome before the fragments may be assumed to have been properly coapted. Fracture in the same part of the radius with displacement in the opposite direction, namely, forward, is frequently unrecognized, and is therefore imperfectly reduced. In this fracture, the general deformity, which Dr. Roberts calls the "Gardener's Spade Deformity," is very characteristic. It is very different from the "silver-fork deformity" of the fracture with backward displacement of the carpal piece. The planes of the forearm and hand are related to each other almost exactly as are the planes of the handle and blade of the gardener's spade. In both lesions the styloid process of the radius is apt to be carried upward toward the elbow. As a result, an imaginary line joining the ulnar and radial styloid processes crosses the axis of the forearm at nearly a right angle or with the radial end nearer the elbow than the ulnar end. In the normal arm this interstyloid line is farther from the elbow on the radial than on the ulnar side. The ulnar head is very prominent at the back of the wrist in fracture with forward displacement; but not so in the break with backward displacement. In both forms of injury, however, this ulnar head may be very prominent at the ulnar edge of the wrist; because the shortening of the broken radius may give a displacement of the hand and carpus toward the radial side of the limb. Examination with the X-ray Dr. Roberts believes to be of aid in diagnosis, though usually it is not needed. The treatment of both fractures, he said, is easy, if the doctor will only use force enough to disentangle the carpal and compel it to assume its normal position. A light, straight splint on the dorsum of the forearm and hand, or a convex splint on the palmar surface is usually the proper retentive dressing after reduction has been thoroughly accomplished.

Dr. Alfred C. Wood agreed fully with Dr. Roberts that the fracture under discussion is one of the most badly treated of all fractures. He believes that in the large majority of cases the shaft is impacted in the lower fragment. He approves of giving an anesthetic to secure reduction when there is much deformity.

Dr. Frank Woodbury referred to the inability at first to give a true prognosis owing to the possibility of comminution of the lower fragment and of the presence of synovitis. He called attention to the recommendation of Dr. Thomas G. Morton to make frequent examinations of fractures, especially of the radius, and the application of hot douching and massage. In the cases he has treated he has not made special effort to reduce the fracture completely at the beginning, but has relied on the later manipulations and has had satisfactory results.

NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 6, 1905.

The President, Arthur P. Hitchens, M.D., in the Chair.

SYMPOSIUM ON INFLUENZA.

Etiology and Diagnosis.—The etiology and diagnosis was read by Dr. G. Morton Illman, who stated that the disease was of very ancient record, being mentioned by Hippocrates, as far back as 400 B.C., and particularly referred to the epidemics of 1847 and 1889-1890. He stated that it is generally defined as an acute infectious communicable disease, characterized by fever and catarrhal irritation of the mucous tracts, and contrasted the theory of Pfeiffer who regarded it as due to a bacillus with others, who felt it was due to a toxemia, and expressed the belief that the latter was the result of the bacillus rather than the cause of the infection. He described the bacillus and stated it as found chiefly in the nasal discharge and sputum. He referred to the fact that the disease in many instances extended over a considerable portion of country, and believed that the communicability was due to an infection, in many instances accentuated by a predisposed system, such as general debility, anemia, tonsillitis, and chronic catarrhal condition of the gastro-intestinal and upper respiratory tract. He stated age and sex played but little part in the condition, the period of incubation is uncertain and but little, if any immunity is afforded by a previous attack, but general conditions, such as climate, heating and ventilation are important factors. The diagnosis, he stated, was not difficult during epidemics, but at other times it was very often confounded with an acute febrile bronchitis, coated tongue, headache, pain in the back, fever, chill, vomiting, vertigo and malaise being symptoms characteristic of many conditions, such as typhoid fever, rheumatism, malaria, and tonsillitis. The writer then distinguished between each of these conditions, and believed that accuracy could probably best be arrived at by a process of exclusion, although the finding of the bacillus is the surest, its staining and isolation is so difficult that it is not always practicable.

Influenza Complicating the Ear and Upper Air Passages.—This was Dr. William Hitschler's paper, and was read by Dr. Butler. He considered first its relation to the ear, and stated that it might affect

either the inner ear of the diseases of which little is known, and to which influenza adds no distinct characteristics, or the middle ear, involving either the drum-membrane alone or the entire middle ear, in which it differs from the ordinary otitis media in that in the early stages of the conditon there is a marked tendency to hemorrhage, which may be observed as punctate or diffuse ecchymoses on the tympanic membrane or as bloody vesicles raised from its surface, sometimes extending beyond the confines of the membrane itself, and involving the posterior-superior wall of the external auditory meatus. The pain is more severe and is more likely to be present on pressure over the mastoid, and the symptoms of tinnitus, deafness and discharge are intensified. The mastoid is much more likely to be involved than in other conditions, and the external attic is often the subject of purulent inflammation. The diagnosis between this condition and severe simple acute inflammation is very difficult, the prognosis is not as good, and the tendency to chronicity greater than in the latter. In the upper air passages, in addition to the usual catarrhal signs, there are frequently whitish-gray patches due to necrosis on the larynx and trachea. Hemorrhage, in the shape of nose-bleed or hemorrhagic laryngitis, edema of the larynx and pharynx and abscesses of the larynx and thyroid gland have also been observed. The recurrent laryngeal nerve is frequently affected and paresis of the soft palate are among the nervous symptoms. He referred to the tendency to sinus disease in these cases, and also referred to the fact that many of the cases get well without, and many are assisted by appropriate treatment, still there are a certain number which result either in chronic sinusitis, or a transmission of the infective process to the orbital or cranial cavities, sometimes resulting fatally, such as fatal meningitis caused by an acute empyema of an accessory sinus, and too often the etiology is unsuspected, and are more likely to occur in acute exacerbations of a chronic sinusitis brought about by some infective process, such as influenza.

Prognosis and Treatment.—This was discussed by Dr. Samuel Wolfe, who stated the prognosis was almost invariably favorable to life, if the patient had none of the senile debilities, and no complications arose. He stated that the prognosis must be considered (1) in relation to life, and (2) as to the liability to complications, on account of the fine field for infection, among the prominent being pneumonia, endocarditis, pericarditis, pleurisy and meningitis. He believed the season of the year had much to do with the complications, winter being particularly favorable to pulmonary involvment, and the summer and fall to gastro-intestinal involvment. He stated that each epidemic was liable to have peculiar complications, and believed that the individuality of the patient and management of the case, as well as the sequelæ, had much to do with the duration of the attack. Among the complications following the condition which he considered in detail were influenza pneumonia, catarrhal bronchitis, etc., and the neurotic affections, such as neuralgia, hysteria, and hypochondriasis. He believed that persons who had once had the disease were more liable to a second attack, and that the treatment should be directed (1) to the fever; (2) to the pain; (3) to the respiratory symptoms; (4) to the gastro-intestinal and nervous smyptoms.

Dr. Lewis S. Somers referred to the remarkable increase in the number of operations for conditions of the accessory sinuses during the last decade, which he felt due partly to the development of surgery, but in a large measure to the increase of morbid conditions thereof, brought about by the epidemics of influenza. He stated that this winter he had seen about 15 to 18 cases of frontal sinus involvement, while in the last three or four years involvement of the maxillary antrum had seemed to be the prevailing condition. He referred to the fact that complications of the upper respiratory tract were comparatively rare in those cases who went to bed immediately upon the onset of the condition. He expressed the belief that in many instances the severe headaches and trifacial neuralgias, following influenza, were the result of catarrhal condition of the accessory sinuses, which theory was borne out by the fact that local treatment of these regions would often remove the trouble. He did not view the hemorrhagic form of otitis as peculiarly characteristic of influenza in Philadelphia, and furthermore felt that in many instances abnormal conditions of the sinuses were induced by improper douching of the nose.

Dr. Swithin Chandler referred to the fact that he had observed a great many women with diseases of the tubes, who stated that it had started with influenza, and while he had viewed these at first as due to a weakened constitution, giving a chance to a latent germ to take effect, he was later inclined to look upon it as rather the introduction of a new germ, causing the germs already in the system to become active, mentioning among the germs that might be so influenced, the gonococci and streptococci. He cited in support of this theory the fact that some cases giving this history operated on some years ago, showed the gonococcus germ quite virulent, and in conclusion urged the necessity for individualizing the cases.

Dr. Carle Lee Felt stated that in his experience there had been very little difference in the middle ear conditions, following influenza and other middle ear conditions, except the severity of the disease, and cited several cases following influenza, in which between the attacks the ears were perfectly normal.

Dr. Frank C. Hammond stated that he had also observed that the pelvic viscera might be influenced during acute attacks, and stated that he had seen three cases, two in single women, both eighteen years of age, who, on the third day, showed marked pelvic involvement. He referred to a case in which there was pain and rapidly increasing leucocytosis in which appendicitis was suspected, but exploratory examination showed the appendix to be perfectly normal, but there was an accumulation of pus in the abdomen, which was evacuated and drainage established, and the woman made a good recovery. She had been in bed about three weeks when this condition arose. He stated that he had under his care at the present time two cases, one with the loss of the sense of taste which had improved somewhat under strychnine 1/30 gr., four times a day, and one with loss of sense of smell which was still unimproved.

Dr. Samuel P. Gerhard referred to the selection of the various mucous membranes as the situs of complications attending or following the influenza, and dwelt upon the importance of producing elimination as quickly as possible. He stated that last fall there seemed to be an epidemic of streptococcic infection, and now, since the epidemic of influenza has been in progress, there seem to be a great many

cases of streptococcic infection complicating that condition. He referred to a case who complained of pain in the back, and on examination he found an old cyst had broken out, and suggested the possibility of the frequent involvement of the mucous membrane being due to some weakened condition.

Dr. P. K. Schwenck referred to the fact that the ear complications following influenza were mostly unilateral. He believed that most of the severe headaches were due to sinus complications, and emphasized the importance of rest in bed as a part of the treatment of influenza. He stated that he had very few mastoid operations following influenza, and believed that involvement of this region was more frequently caused by other conditions.

Dr. Butler, in closing, stated that in the early stages many of the cases of sinus involvement were merely congestion, and consequently anything that would relieve the congestion would relieve the condition. He also believed that the number of cases of mastoid involvement had been materially increased by the epidemics of influenza. He stated that he had never seen anything in the literature about unilateral involvement, but that it was not uncommon either in otitis media or in eustachian tube disease.

Dr. G. Morton Illman stated that he always warned the patients in the later stages, after the mucus began to collect, against blowing the nose too vigorously, and referred to two cases which had come under his observation last winter, and one this winter, of infection due to too vigorous blowing of the nose. In regard to the use of potassium iodide, he stated that, while he had been able to abort an attack of influenza, he believed the cases were more frequently complicated by otitis.

Dr. Samuel Wolfe, in closing, stated that, while he was in the habit of using considerable potassium iodide in conjunction with other drugs, he had not given it in large doses for abortive purposes. He felt that probably the complications following its use were due to the stopping of nature's methods of elimination. He referred to the frequency of the mucous membrane being the site of complications, and stated that he did not believe cases of pelvic involvement were necessarily secondary infections.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

SYMPOSIUM ON THE BLOOD PLATELETS.

Regular Meeting, held March 6, 1905.

Dr. Osler gave a résumé of the history of the subject. The blood platelets had, he said, attracted a great deal of attention between 1857 and 1867 after the appearance of Schulze's original article in the *Archiv für mikroskopische Anatomie;* and their clinical significance was promptly studied by Ries, who wrote the first paper on this subject. In 1873 Osler, working in London, noticed peculiar bodies in the blood of subcutaneous and mesenteric vessels of white rats; and these he found to be the individual elements of Schulze's granule masses or agglutinated plates. Zimmermann had seen the same things previously and had called them elementary corpuscles. When watched on a warm stupes Dr. Osler and others noticed marked changes rapidly taking place in the platelets which became elongated and diamond-shaped and finally appeared as threads. It was suggested that they might be parasites; but in 1878 Hayem, in a large work on the subject, called them hematoblasts, testifying to his belief that the platelets played a rôle in the genesis of red blood corpuscles. Bizzozero then showed the platelets to be individual elements and studied their relation to the red blood corpuscles working along the lines of Ranvier's previous suggestions. Next came the demonstration of the importance of platelets to blood coagulation—the work of Eberth and Schimmelbusch, which was followed by Osler's observation that white thrombi were made up largely of platelets. Modern study of the question has been concerned with determining whether the platelets were independent blood elements, whether they were precursors of the red blood corpuscles, or whether they were artefacts due to cellular disintegration. The platelets have been usually overlooked in routine examinations; and their association with disease has not been carefully studied—though great increase in the wasting diseases was noted by Osler long ago.

Histology of the Blood Platelets.—Professor Kemp, of Champaign, Ill., said that in the relatively few years that blood platelets had been known enormous literature had sprung up on the subject. The platelets were best studied, he said, after immediate fixation, or by working in a low temperature and with cold glassware when the changes in the platelets were slow and could be watched. At the end of some minutes (when studied at 40° F.) they became granular, irregular in form, gradually lost their individuality, fused into a mass and finally broke down. *Pari passu* with these changes came the clotting of the blood, the fibrin being deposited thickly about the blood platelets but independent of them—though the possibility of coagulation with intact platelets had never been proven. A smear of blood passed rapidly into salt solution (to wash off the corpuscles) and then put in one per cent. osmic acid gave a beautiful fixation specimen of platelets. There has been a good deal of discussion as to whether oval, discoid platelets were biconcave or not—due, probably, to the change in shape which occurs with the change in containing fluid. They probably do not contain hemoglobin, though Professor Kemp said that he had seen platelets, during some observations at a high altitude, which seemed to be exceptions to this statement. Their function is still a debated question, though it seems probable that they are hematoblastic. The figures given by Arnold, which the author thought proved the platelets to be degenerated red cells, probably represented artefacts. Löwit thought the platelets to be precipitated globulins and not true blood elements; but their observation by Osler within the blood-vessels and later by Bizzozero's son in the frog's mesentery and the bat's wing, seem to prove them independent elements. They are best counted by the indirect method—determining first the red blood count and then the ratio of platelets to erythrocytes. Professor Kemp found experimentally that if blood from an artery be defibrinated and injected back into a vein, the platelets (after sufficient repetition of defibrination and injection) disappeared and the blood refused to clot.

Relation to Disease.—Dr. J. H. Pratt, of Boston, referred first to the great confusion existing in the literature as to the platelets and said that there were marked differences beween these Arnold bodies, which were artefacts, and true platelets. A good preparation of them could, he said, be prepared by fixing the smear in a solution of sodium metaphosphate in sodium chloride. Stained by certain methods chromatin may be shown in them and a pseudo-

ameboid movement has been observed. In health the number of platelets varies greatly but they average about 300,000. Dr. Pratt reported a series of diseased conditions with the plate count in each. The lowest count (7,000) was made in a case of purpura hemorrhagica. The platelets were never absent but were greatly reduced in number in lymphocytic leucemia (series of 8 cases, count varying from 10,000 to 94,000) and in pernicious anemea (series of 10 cases). In secondary anemias they may be increased—a point which may be of diagnostic value in distinguishing from primary anemia. An increase in platelets was found in myelogenous leucemia (count varying from 50,000 to 1,498,000), in chlorosis, in erythrocytosis and in *severe* hemorrhage. Dr. Pratt thought the evidence was conclusive for regarding platelets as third corpuscles.

Dr. Emerson said that he had often seen pseudopsia extruded from platelets, but never any real ameboid motion with progression. The endoglobular degenerations of Maragliano had been shown to have a distinct existence; and it was possible that the platelets might represent extruded "innere Körper," or might be due to the disappearance of the red blood cell from about the "innere Körper" and nuclear material. Dr. Osler said that the changes seen in the platelets were similar to the mechanical changes occurring in red blood corpuscles, and were not truly ameboid. The great number of platelets in embryos and in wasting diseases had never been explained. Dr. Boggs referred to recent work done in Germany in reference to the relation of platelets to coagulation. It was found that if fibrinogen be treated with a mass of pure blood platelets coagulation occurred rapidly, but took place much more slowly if leucocytes were used instead of platelets.

NEW YORK ACADEMY OF MEDICINE.

Orthopedic Section.

Stated Meeting, held February 17, 1905.

The President, Homer Gibney, M.D., in the Chair.

Pott's Disease of the Spine.—Dr. Jäger presented this case: Symptoms began about April 1, 1896. Mother first noticed child holding head forward, and he complained of pain in back and side of neck. Examination at that time showed a well-nourished, healthy boy; walks with head slightly forward. A prominence at about the sixth cervical,—spine below seventh cervical flat and rigid. January 5, 1897: Child in good condition, wearing brace since previous May. No increase of deformity. He wore the brace off and on for two years, then discarded it. There were no symptoms until four years ago, when a boil formed on inner side of right shoulder blade. It was poulticed and broke open, and has been discharging ever since. Two years ago another abscess formed under left shoulder blade. This was opened, and has remained open ever since.

He has had general medicinal treatment—carbolic washes—but has worn no brace. His appetite has been good, he sleeps well, and gets about without any trouble. Lately he has complained of pain in back and shortness of breath. Now the boy holds head bent forward. Examination of spine shows but slight deformity, and the tracing to-day is almost identical with the tracing taken nine years ago. There are two discharging sinuses. A review of the literature shows that disease of the laminæ is very rare. The only reference to a similar case was in the *American Journal of Surgery and Gynecology* for April, 1903, where Eastman (St. Louis) describes a case in an adult.

Report of a Case of Osteitis of the Spinous Processes and Laminæ Simulating Tuberculous Disease of the Body of the Vertebra, or Pott's Disease.—Dr. Reed, House Surgeon, Hospital for the Ruptured and Crippled, (by invitation) read this paper and exhibited this patient: Frances C., aged six years, was admitted to the Hospital for Ruptured and Crippled, June 13, 1904, diagnosis of Pott's disease of the lumbar spine. She was admitted for the relief of an abscess. Nothing definite could be learned in the way of a history. She had been living near St. James, Long Island, for the last three years, and the deformity was not recognized for a month prior to her admission to the hospital. During this month it had rapidly increased, and she presented on admission uniform posterior curvature of the spine from the upper dorsal to the sacrum, but no angular deformity. There was a good deal of infiltration on either side of the spinous process, with tenderness, but fluctuation was not made out. There was a little psoas contraction on the right side, but no psoas abscess was discovered. She was put on a Bradford frame, and two months later the psoas contraction had disappeared, but there could be made out fluctuation over the spinous processes of the dorsolumbar. In December, five months after her admission, there was a distinct tumor and fluctuation under the gluteus maximus muscle on right side, and this infiltration on either side of the spinous processes had rather increased, but there was no marked fluctuation on the left side. The spinal deformity was, if anything, less pronounced. On the morning of February 14 an incision was made through the gluteus maximus down through the sac, and about six ounces of pus, with some caseous material, was evacuated. After it was thought to be completely emptied, the opening of the sac was sutured with catgut, and the skin also sutured. Then an incision was made a little to the right of the spinous processes of the eleventh and twelfth dorsal, and thick, caseous material was squeezed out to the amount of about three or four ounces. There was very little fluid. By pressing firmly over the left side as far up as the upper dorsal this material was forced out of the lower opening. A director came in contact with loose bone. The gloved finger was inserted, and the spinous processes of the lateral masses were felt completely eroded. This large sac was thoroughly cleansed with sterile gauze, and the same care taken in suturing as in the other abscess. At this time the abscess under the gluteal muscles was found to have completely refilled, and the wound was reopened and three or four more ounces of pus evacuated. After it was thoroughly emptied again it was resutured, the child put up in a plaster-of-Paris jacket and spica, and put to bed. Up to the present time there has been little or no reaction, the temperature is about normal, and the case is doing well. Microscopical examination of the pus evacuated showed pus and blood, but no bacteria of any kind.

Dr. H. C. Frauenthal presented a case about which, he said, there was nothing unusual except for the fact that he had worn a jacket for twelve years at Bellevue. He said, in his experience, many patients were discharged as cured after wearing a jacket for various periods, and he wished to show this case as exhibiting the effects of after-treatment. When this young man was discharged he had the charac-

teristic color of patients whose breathing has been restricted for a considerable time. The boy had now a ruddy complexion and an increase in chest expansion of three inches, which change had resulted from physical culture begun in May last—a period of ten months.

Colles Fracture.—Dr. Ashley showed this case. It gave an idea of how much damage such a fracture might do, and the result: Three years ago this boy had a Colles fracture. He was put up with anteroposterior splint. Had great pain and swelling. Hot applications were advised by the physician and used for about a week, and the present condition is more the result of the anteroposterior splint and hot applications than of the fracture. There is a massing of all the tendons. The arm can be straightened, but there are deep scars, due to hot applications applied with the brace. The muscles are all adherent to the scars. The palm was very much contracted, and has been a great deal worse than it is now. The styloid process had been broken or partially dislocated, and the bone was atrophied there. Also some results of the inflammatory process were seen. Nothing had been done until six months ago, when it was straightened by force, and an effort was made to liberate the tendons. At the wrist a transverse incision was made and an effort to reduce the tension upon the palm. His local doctor had treated him by massage. The flexor longus pollicis tendon is rigid. The boy has no power to flex the thumb. Dr. Ashley said he had another case exactly like that in a clinic, that came to him immediately after the injury. It was not so badly scarred as that, and by manipulating it and afterward giving massage, a perfect functional result was obtained. The injury in this case shown to-night occurred three and one-half years ago.

In response to questions, Dr. Ashley said he had tried to loosen the tendons under an anesthetic, and that wrist is loose now compared to what it was. The X-ray showed exactly what the position was before anything was done to it. It did not show the dropping of the wrist so well.

Dr. Jäger described a simple device, gotten up by Schade, in Dresden, for exercising the hand after an injury or phlegmon. It consisted of a series of highly polished wooden rods twelve inches long, graduated from two and a half inches down to the thickness of a lead pencil, with a hook at the end of each, to be fastened to a Whitely Exerciser, or similar apparatus. The patient begins with the largest rod and pulls. If the grasp be not sufficiently strong, it slides out of the hands. Next time he will concentrate his mind, and hold harder. By this scheme of treatment the patient can see if he does not exercise properly. He works at the large rod until he acquires a good, firm grip, then takes a smaller one, so on until the smallest is reached.

Dr. H. C. Frauenthal showed a case in line with the paper he had read at the last meeting. He had several such cases—women between the ages of forty and fifty—but the others could not come. One of them has almost complete anchylosis in both wrists; no motion. Exostosis is same as this woman's hands. This patient had had innumerable doctors and all kinds of treatment—specific—here and at various springs. He thought the trouble due to gonococci. Whether this be true or not, it had yielded to treatment he had given—galvanic current and baking. She had had little internal treatment except laxatives. The joints of hands and feet were excruciatingly painful. No cultures had been made. The trouble had existed eight or ten years—mixed infection, if anything. Dr. Frauenthal thought these joints the kind referred to by Dr. Northrup in the discussion at the last meeting, as cured by this treatment, which had greatly benefited the speaker's patients. This woman had been unable to walk a block without resting, or go upstairs. In a month, after two or three treatments a week, she was much improved.

Dr. Homer Gibney said such cases were frequently seen at the Hospital for Ruptured and Crippled, and they were thought to be rheumatoid arthritis. Perhaps they were cases of gonorrheal infection, but it did not necessarily follow that this case was, as Dr. Frauenthal had no means of establishing it.

BOOK REVIEWS.

The Thyroid and Parathyroid Glands. By Hubert Richardson, M.D., Pathologist to Mount Hope Retreat; Pathologist to Maryland Asylum and Training School for Feeble-minded Children; Demonstrator of Physiological Chemistry, University of Maryland. P. Blakiston's Son & Co., Philadelphia.

No one who has followed the brilliant discoveries in organotherapy through the recent years, and has noted the far-reaching possibilities laid open by this study, can fail to show interest in Dr. Richardson's new book. He has conscientiously collected all the data upon this subject from the existing literature, and by means of his own wide knowledge of and experience with these therapeutic agents has produced a volume of exceeding interest and value. The author first presents the historic and scientific phase of the subject, giving the anatomy, physiology and chemistry of the thyroids and parathyroids. Following this, he fully describes the diseased conditions to which they are liable and their dependent functional alteration. Finally, he shows their value as therapeutic agents and the lasting benefit to humanity the knowledge of their use has contributed.

The work done upon this subject has furnished a most luminous chapter to medical science, and this volume can be recommended as an entertaining and competent dissertation upon this, as yet not widely known, subject.

Conservative Gynecology and Electrotherapeutics. By G. Betton Massey, M.D. F. A. Davis & Co., Philadelphia.

The shocking neurotic conditions often resulting from the wholesale unsexing of women has produced among modern gynecologists a reaction toward more conservative operative procedures. This point of view is evident, as indicated by the title, in Dr. Massey's recent volume.

Since the appearance of the third edition (1898), Dr. Massey has spared no pains to bring his book thoroughly abreast of recent observations and discoveries.

In Part I he finely presents the application of electrotherapeutics to the various female disorders, clearly and copiously illustrating his contentions by reports of numerous cases, and by means of excellent drawings and halftone reproductions.

In Part II he elucidates the rudimentary principles of medical electricity, the knowledge of which has become an absolute essential to the armamentarium of every practising physician. His treatment of this subject is satisfactory and sound, but it is difficult to view the extensive application of the principles in the same spirit of enthusiasm as the author.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 87. NEW YORK, SATURDAY, JULY 15, 1905. No. 3.

ADDRESSES.

THE AMERICAN MEDICAL ASSOCIATION: ITS ORIGIN, PROGRESS AND PURPOSE.[1][2]

BY LEWIS S. MCMURTRY, A.M., M.D.,
OF LOUISVILLE, KY.

BOTH established usage and the by-laws of this Association require the presiding officer to deliver annually an address touching such matters as he may deem of importance. In the early years of the Association the President's address was devoted to an epitome of the progress of medical science in its various departments during the preceding year. Since distinguished orators are now selected annually to perform this important service, the President's address may be more appropriately directed to subjects relating to the general welfare of the profession and to the purposes for which this great organization was established.

The annual session of the American Medical Association is always an occasion of special moment and universal interest in the medical profession of America. That several thousand physicians from all sections of our broad country assemble annually for the advancement of medical science and the elevation of our profession is a splendid testimonial to the earnestness of professional achievement and aspiration. The occasion cannot but command the respect of all who are concerned in the progress of science and the betterment of the human race. The spirit which pervades such an assemblage is the desire for improvement, for the increase of scientific resources, and for the diffusion of medical knowledge. Closely related to these ennobling purposes is that social instinct of our profession, which would elevate and be elevated by interchange of views resulting from common experiences, and by mingling together in pleasant friendly intercourse. Happily our present meeting is held under ideal conditions for the exercise of all the functions of such an organization. Perfect harmony prevails. The differences which at times have divided us have all been satisfactorily adjusted; and we are to-day as one man in our united effort to advance the science of medicine, to enlarge the scope of its beneficence, and to promote the welfare of our profession.

Since our meeting at Atlantic City one year ago, many of our members have ceased their labors and passed to the great beyond. The list is a long one. Among the number is that of Nathan Smith Davis. He was one of the founders of this Association, an ex-president; a member of the Board of Trustees, the first editor of the *Journal of the American Medical Association*, and for years a power for good in its affairs. He lived beyond the time allotted by the Psalmist, and all his years were filled with labor and with honor. I will not undertake at this time to estimate adequately his great services, or appropriately to pay tribute to his memory. This will be done later in the session by one better prepared than I to eulogize our departed leader.

At our last session, Dr. B. C. Pennington, of Atlantic City, was chairman of the Committee of Arrangements. He was honored with the fourth vice-presidency in recognition of his ability, his high professional standing, and his devoted services to this Association. His name, too, is now found among the year's honored dead. A cultured gentleman, a learned and accomplished physician, his memory will ever remain as an inspiration for high ideals and noble endeavor.

Early Years.—When the American Medical Association was organized in 1846 it is doubtful if there were more than 25,000 physicians in the entire United States of America. It was organized as a representative body, composed of delegates from affiliated societies, colleges, and hospitals throughout the States. It was a body of delegates from all State, district, county and other medical societies which adopted the code of ethics of the national association. The apportionment of delegates was on a basis of one for every ten members of the societies represented. For a number of years the delegate body thus constituted was not too large for the discussion of important subjects and the ready transaction of business.

With the rapid increase in population, the admission of new States to the Union, and the settlement of new Territories, came a vast increase of physicians, with a corresponding multiplication of State and county societies. Without change in the apportionment of delegates, the national association developed into a body too large and unwieldy for the transaction of business. Indeed, during the latter years under the original system of organization, practically every member in attendance on the annual sessions was a delegate. While the work of the sections was carried on with increasing excellence, the important functions relating to legislative and other matters, belonging to a great national organization of the medical profession, were neglected. The general sessions brought together hundreds of delegates, forming a convention so large that thorough discussion of important questions and judicious action on the same became practically

1. President's Address, at the Fifty-sixth Annual Session of the American Medical Association, at Portland, Oregon, July 11 to 14, 1905.

2 Courtesy of the Journal of the American Medical Association.

impossible. Moreover, the delegates attending the annual sessions constituted a body annually changing in personnel; and the sources of attendance changed with the sections of the country in which the meetings were held. In consequence there could be neither that equal representation of all sections which must obtain in a national body, nor continuation of work from year to year along definite lines.

The Sections.—During these early years it was the steady improvement in the work of the sections which drew the best element of the profession to the annual sessions. Many leaders of the profession in the various States attended the sections in which they were interested, and took no part in the proceedings of the general meetings. The sections have now reached such a high degree of efficiency that they have attained the standard so much desired, and rank as leading special national societies in the several departments of medical science which they represent.

As chairman of the Committee on Sections and Section Work, I have carefully studied the workings of the sections. As a result of this experience, I would repeat the recommendation of my distinguished predecessor in this chair, that the secretary of each section should be elected for a term of years. No national society can maintain its efficiency which changes its secretary annually. And again, I would suggest that the officers of the several sections meet together in conference as soon as practicable after the adjournment of the session at which they are elected, in order that definite plans may be formulated for the scientific work of the next annual session. The conference of section officers in New York last November contributed much toward the development of the admirable scientific program now before you for the present session.

It should be the aim and purpose of every member of this Association to aid the officers of the sections in elevating continually the standard of scientific work. Every American physician may have pride in the work done year after year in the sections of this Association.

The Journal.—It would be a difficult task were we to undertake a definite estimate of the influence of *The Journal* in the great work which this Association has accomplished during the past two decades. When it was decided to discontinue the annual volume of transactions, and to establish a weekly journal, the change was viewed with apprehension by many. The influence of this publication, the property of the Association, in stimulating research, diffusing knowledge, elevating professional thought and conduct, and building up this great organization cannot be computed. This part of my discourse is so replete with suggestion, that I fear the time and space at my command will not permit such consideration as should be devoted to it.

The volumes of *The Journal* mark the steady and continued growth of the Association, and likewise bear testimony to the fact that *The Journal* itself has been a potent factor in that growth. Under the judicious direction of the Board of Trustees *The Journal* has steadily advanced as a scientific publication. By the untiring daily services of the present able Editor, it has leaped into the very front rank of scientific publications, and in all that a great weekly medical journal should be it has no superior in the world. The power exerted by such a publication as a medium of communication among the members of the Association is inestimable, to say nothing of the other more important functions performed by a great weekly journal. It has been the most potent instrument in building up this Association to its present proud position as the largest medical organization in the world. No other American medical periodical has a circulation so distinctly national, and no other journal can sustain the same relation to the great body of the medical profession. It is a great engine whose power is constantly increasing, constantly extending. With such increased power comes increased responsibility, much of which rests with the House of Delegates in the selection of proper men to fill the responsible places of the trustees. No other office should be regarded higher in honor than that of the trustees, as no other affords greater scope for unselfish labor and efficient service to the Association. Under the conditions of our organization more power is invested in this board than the combined power of all other officers.

The New Era.—At the annual session of 1900 a committee on reorganization was appointed, and one year later, at St. Paul, the report of the committee was submitted and adopted. It included a new constitution, which altered the basis of apportionment for delegates, so as to reduce the delegate body to 150, and definitely established a close relationship between the national organization and the State, district and county societies. For the first time a practical scheme of complete organization of the medical profession of the United States was provided. This is the fourth annual session held under the new plan of organization.

Previous to the reorganization, the valuable scientific work of the sections constituted almost the sum total of the effective work accomplished by the Association. Matters appertaining to medical education, to the public health, to national legislation, and to the welfare of the profession received no deliberate consideration; and in consequence no decisive action was carried out. This condition existed for the reasons already mentioned. In a word, the very objects and aims for which the Association was organized were thwarted by the growth of the Association into an unwieldy delegate body. Under the reorganization, the House of Delegates, in which the membership of the State societies is proportionately represented, now gives deliberate consideration to those important matters, already

indicated, which under the former organization were neglected.

The influence of the revised plan of organization was immediately apparent in the increased attendance at the annual sessions, and the stimulus felt in every purpose of the Association. And each year this influence has grown, until some idea can now be formed of the great possibilities to come from organization on a definite and practical plan. The good results to accrue to the profession as a whole, and to every member as an individual, are so positive that no subject can deserve more careful consideration by this body than that of medical organization. Indeed, it is the fundamental question before us, and on its decision depend the results of all our other efforts in all directions.

In order that we may thoroughly appreciate the origin and purposes of the Association, and thereby be better prepared to meet its present and future requirements, I have very imperfectly outlined the history of its earlier years. During the more than half century of its existence it has always brought to its councils the ablest and best men in the profession of America. Among its leaders from the beginning are found the most eminent physicians and surgeons of the day. In the list of its active members are the names of Samuel D. Gross, Paul F. Eve, Austin Flint, Marion Sims, N. S. Davis, Alfred Stillé, Lewis A. Sayre, and many others which adorn the annals of American medicine. It has from the beginning been a great power with the profession of America. Its greatest influence, as I have already indicated, was in the growth and diffusion of scientific knowledge through the splendid work of the sections. In elevating medical education, in promoting legislation, and advancing the powers of public health organizations its influence was most felt in the development of a helpful public professional opinion. The extension of the influence and advantages of organization to the masses of the profession was gradually lost sight of in the annual meetings, and the work relating to matters of public policy was spasmodically considered and imperfectly executed. Whatever was accomplished along these lines worthy of mention was the work of committees. The necessity of reorganization was appreciated by the leading members of the Association long before it was accomplished. in 1888, Dr. N. S. Davis, as chairman of a committee appointed for the purpose, reported a scheme of reorganization very similar to that adopted in 1901 at St. Paul.

"*Organization.*—The object of this Association shall be to federate into one compact organization the medical profession of the United States, for the purpose of fostering the growth and diffusion of medical knowledge, of promoting friendly intercourse among American physicians, of safeguarding the material interests of the medical profession, of elevating the standard of medical education, of securing the enactment and enforcement of medical laws, of enlightening and directing public opinion in regard to the broad problems of State medicine, and of representing to the world the practical accomplishments of scientific medicine." (Article II, Constitution of the American Medical Association.)

If every physician worked alone, relied on his own unaided observation for his knowledge, never looking outside his own scope of view, ignorance would prevail and there would be no progress in medical science. Medicine is not an exact science, and until perfected by extorting from Nature all her secrets, it must from the nature of things continue to be a progressive science. Never before in the history of medicine has such marked progress in all its departments been made as during the present age. Theories have been supplanted by facts; laboratory research and clinical investigation have taken the place of tradition and authoritative opinion. To rely on the accomplishments of the college period is to be left behind in hopeless incompetency. The advance of medical knowledge is to be observed first in our medical societies, and afterward in our scientific medical journals. In the medical societies innovations are subjected to criticism and discussion by those competent to judge the merits of scientific contributions. Moreover, there is a stimulus to study and investigation from association with workers in the same field; and one obtains a broader view of every subject so considered. The physician, more than any other professional man, is isolated by the conditions of his life, and to no profession is the educating influence of society work so essential and invaluable. This same condition of isolation is at the foundation, for the most part, of the jealousies and petty bickerings so prevalent in our profession. These troubles are, as a rule, the result of misunderstandings, and are both prevented and corrected by coming together in a society composed of physicians. The lonely worker in any calling is prone to become narrow, suspicious and morbid. Our medical societies are the great postgraduate schools of the profession, where knowledge is increased and individual character developed.

But the promotion of scientific investigation, and the diffusion of medical knowledge are not the only objects of organization. Our profession has a most essential and important duty in relation to the public health. Through no other agency can municipal, State and national health authorities formulate and secure recognition of laws to prevent and control disease. Another duty no less essential is to regulate and to control medical education that the ignorant and unworthy shall not be admitted to the privileges of the profession, thereby preserving the time-honored standard of professional honor and scientific capability. In this age of organization, without it the profession is powerless to secure the enactment of humane sanitary laws, by which alone the people can be protected from

preventable diseases. The welfare of the profession, collectively and individually, can only be subserved by organization. Without such organization, our profession, as a body politic, will be without unanimity of sentiment or action in relation to the important scientific, ethical and social questions which confront us; and consequently without influence, politically, socially or otherwise.

In the declaration of the constitution adopted at St. Paul, which I have just quoted, the American Medical Association has undertaken to place within reach of every reputable medical practitioner in the United States these incalculable advantages of medical organization.

The Committee on Reorganization appointed in 1900 has treated this subject in a masterly manner. After a careful study of the condition of the profession throughout the States with relation to organization, reports have been made to the Association showing the needs of the profession and the extent of the work required. A uniform plan of organization for State and county societies, making the county society the unit of organization, and federating all State societies in the national association in harmonious cooperation, has been prepared by the committee. The able chairman of this committee has, with remarkable tact, patience, and good judgment, given his personal supervision to this great work in almost every State and Territory. In his latest report it is announced that all the States and Territories, except three, and including Hawaii and Porto Rico, are now organized on a practically uniform plan, with universal local societies, and coincident membership in them and the State associations are the cardinal feature. To illustrate the magnitude of this work, I mention that, under the stimulus of reorganization after the plan of the committee, the Michigan State Medical Association increased in membership in one year from 452 to about 2,100. Texas increased the membership in the same time from 382 to 2,510, while several States quadrupled their membership. While these results are phenomenal, and elicit our admiration, it will be realized how much remains to be done when it is considered that few of the States have over 50 per cent. of the eligible members of the profession enrolled as members of the society. Indeed, the work is yet almost in its infancy. What has been accomplished is an assurance for the future; and considering the brief time since reorganization began, is a high tribute to the enterprise of the national association and the work of its able and efficient committee. The possibilities of this work are stupendous, and as it proceeds the Association can confidently undertake the great reforms of such incalculable moment to the profession and the public. In his official report to the House of Delegates one year ago, the chairman of the Committee on Organization, after reporting his labors during the year, said:

"The real test of our organization will come in each State when the first outburst of enthusiasm has passed, and county societies, the foundation for everything, are likely to disappear as rapidly as they have been formed, unless their usefulness to the rank and file of the profession can be demonstrated in a very broad way."

In recognition of this fact, it is of the utmost importance that the personal attention so effectively given to this work throughout the States by the chairman of the committee be continued.

Medical Education.—When the American Medical Association was founded in May, 1846, the delegates assembled in response to the following preamble and resolutions of the Medical Society of the State of New York:

"Whereas, It is believed that a national convention would be conducive to the elevation of the standard of medical education in the United States, and

"Whereas, There is no mode of accomplishing so desirable an object without concert of action on the part of the medical societies, colleges and institutions of all the States, therefore be it

"*Resolved,* That the Medical Society of the State of New York earnestly recommends a national convention of delegates from medical societies and colleges of the whole Union, to convene, in the City of New York, on the first Tuesday in May, in the year 1846, for the purpose of adopting some concerted action on the subject, set forth in the foregoing preamble."

From this it is apparent that this Association was founded with the avowed and specific purpose of elevating the standard of medical education in this country. This subject has constantly received consideration from the Association throughout the years of its existence; and while no distinct and positive reform marks its action, the perpetual demand for improvement undoubtedly molded the public sentiment of the profession which ultimately stimulated action on the part of the medical colleges. Since the addresses of my two distinguished predecessors, who immediately preceded me in this chair, were devoted to the consideration of medical education, I shall only make brief allusion to this subject. The several national organizations and the many State boards which are now dealing with this important professional problem invest the changing conditions with peculiar interest. The present is a transition period in the advancement and reform of medical education in America.

The consideration of this subject in the House of Delegates culminated in the establishment last year of the Council on Medical Education of the American Medical Association. During the past year the council has taken up its work with exceptional energy and good judgment, and is directing its efforts along most practical lines. The first annual conference was held

in Chicago April 20 last. Representatives of many State examining and licensing boards, of the American and Southern Medical College associations, and of the government medical services, attended and participated in the discussions of the papers presented. The plan and scope of the work of the council can be best appreciated by a consideration of this extract from the address of the distinguished chairman of the council delivered to the conference:

"What we need is cooperation, especially the cooperation between the medical profession, represented by the American Medical Association, and the State and county medical societies, and the State authorities, represented by the State licensing and examining boards. The most important question, therefore, before this conference is, How can the American medical profession and the State licensing bodies cooperate to elevate and control medical education? It is believed that such cooperation is possible. In such cooperation it will be the function of the American Medical Association to represent and possibly mold the opinion of the medical profession, and employ its influence and the influence of the county and State medical societies in obtaining proper medical legislation. In such cooperation it will be the function of the State licensing bodies to protect the interests of the public and the profession by seeing that the medical laws are properly interpreted and enforced, and from their intimate knowledge with the medical acts they can often be of service in securing or modifying medical legislation.

"It is not the purpose of the Council on Medical Education of the American Medical Association to attempt to arrogate to itself any special powers, nor does it desire either to criticize or interfere in any way with any of the agencies which are already in the field. If its creation is to result in good, it must be the means of obtaining cooperation between the medical profession and the medical schools, the colleges of arts, the State examining boards, the government services, and all the factors which are interested in elevating and controlling medical education."

By securing cooperation of the various State and national bodies engaged in this important work, recognizing the varied interests involved in the numerous States of the Union, and fostering an intelligent public sentiment, so essential for every great reform, the influence of the Association will be of the most effective character.

Medical Legislation.—Chapter VII, Section 3, of the by-laws provides a permanent Committee on Medical Legislation "to represent before Congress and elsewhere the wishes of this Association regarding any proposed legislation that in any respect bears on the promotion and preservation of the public health, or on the material or moral welfare of the medical profession." This committee was appointed in 1903, and under the leadership of its accomplished and energetic chairman proceeded at once to organize the auxiliary committee provided in the by-laws. This being a permanent committee, its work will be continued from year to year. With the auxiliary committee, representing every State in the Union, and the several medical departments of the Government service, every representative of the people in Congress can be reached directly. The importance of this work is so apparent that I need only call attention to it at this time, and urge on all members of the Association the necessity of aiding and cooperating with the committee at all times. The disregard of the good work of the medical profession in the public service (to say nothing of the indignities offered) on the part of Congress is notorious; and it is only by such concentrated power of the profession, intelligently directed, that such injustice may be overcome. I commend to your consideration the report of this committee in order that you may appreciate the important work already projected.

Council on Pharmacy and Chemistry.—The use of proprietary medicines in the treatment of diseases has become one of the most confusing and demoralizing questions of the day. All proprietary medicines must not be classed as secret nostrums, for there are many honestly made and ethically advertised proprietary preparations that have therapeutic value and that deserve the approval of the medical profession. But there are many preparations offered the profession, which are protected by copyright or trade-mark, with formulæ more or less fictitious, and for which are made extravagant claims, which are in fact secret remedies. These preparations are so exploited by the manufacturer that the physician is persuaded to use them instead of writing a prescription; and since they usually bear popular names and plausible therapeutic claims, they appeal to the fancy of the laity. The field is an enticing one for commercial enterprise since these preparations in many instances are simple mixtures and contain the most inexpensive drugs. The use of such remedies is both unscientific and unjust, alike to physician and to patient.

The separation of the legitimate pharmaceutical preparations from the class of fraudulent nostrums described is a most difficult undertaking. This perplexing problem forced itself from year to year on the attention of the Board of Trustees in the effort of the board to keep the advertising pages of *The Journal* free from unethical advertisements. In order to have thorough protection and to make no unjust discrimination, the board has established the Council on Pharmacy and Chemistry to make the necessary investigations. The council is composed of pharmacists and chemists of national and international reputation. It will be the aim of the council to publish in book form, a list of the preparations which are not official, yet which conform to the proper ethical standard. The

work of the council will be similar to that of the Committee on Revision of the United States Pharmacopœia.

The magnitude and importance of this work is such that I desire to direct attention to it here, and to commend it to the members of the Association as deserving every possible aid and advancement. It is the only practical way to deliver the profession from one of the greatest curses that ever came on it.

It has been my endeavor on this occasion to outline the plans of the founders of the Association, briefly to trace the evolution of those plans throughout half a century of progress, and to recount some of the purposes that invite our active exertions at the present time. From a small body of delegates our Association has increased until it is now the largest medical organization in the world. It owns valuable property, has accumulated a considerable fund, and has a large annual income, all of which belongs to, and is subject to the control of, the members who through their delegates select the Board of Trustees to manage their funds.

The possibilities of the work before us are almost beyond calculation. In acting as the representative and agent of the 120,000 physicians of the United States, the Association is assuming great responsibilities, which will increase from year to year. It will require administrative and executive ability of the highest order to meet these demands; but there is both prophecy and proof in the work already accomplished that men will appear as needed to discharge the supreme duties of a great profession in behalf of science and humanity.

THE DELAY OF OLD AGE AND THE ALLEVIATION OF SENILITY.[1] [2]

BY CHARLES G. STOCKTON, M.D.,
OF BUFFALO, N. Y.

In 1805, Lewis and Clark, typical and celebrated among American explorers, turned their faces toward the furthest west and disclosed in a single expedition the possibilities of the continent and the mysteries of the great undiscovered. Their feat was in principle but a repetition of the undertakings of Columbus, De Soto and La Salle, of Daniel Boone and the numberless pioneers who so quickly, almost suddenly, transformed America from a desolate wilderness into the puissant commonwealth of to-day. In each we may discern a discontent with the established order and environment of his heritage; an inspiration to find in newness a satisfaction which the settled regions, settled habits of thought, settled manners of life failed to provide him at home. The word "settled" is significant. Our race is without rest until it settles things; and with this there stalks a poignant impatience with the things that are settled. The new, the undiscovered, the unattained, the unprecedented, this it is which charms American manhood. The Muezzin calling his prayers from a minaret in far away Cairo, the yellow haze in the circumambient air, the camels with jingling bells, the palms turned always eastward by the hot breeze from the monotonous sands,—these possess for the western man no attraction greater than that of poetic interest. In these scenes he could never make his life. The European finds in America everywhere that which impresses him with our youth; in the Orient, he sees the indisputable evidence of age and a settled order of things. This exploitation of new lands, the cry of "Westward Ho!" which for the past few centuries has stirred mankind, is rapidly, inevitably dying out; but during the long period of its continuance it has wrought important changes in our point of view, it has stimulated a luxuriant growth of thought, it has modified considerably our nature. As our common interest has been fixed upon the untried, we have gradually come to exaggerate the importance of new truths and to ignore the meritorious which the slow moving caravan of thought has brought us from the ages.

Now, it may seem a *non sequitur,* but reflection leads one to inquire if the great appreciation which we feel for the vigorous youth-spirit of recent times, has not educated us to prize, perhaps to overvalue, youth, to the disparagement, if not to the absolute neglect, of old age.

In saying this we are not unmindful of the element of truth in the right interpreted utterance on this subject of one of our most distinguished colleagues. From the standpoint of the original investigator, as from that of the soldier, or the adventurer, there is nothing to replace the effort of the man under forty; but if for no other reason than to obstruct impetuosity and to provide such a handicap that youth shall not too soon outrun the limitations which a wise Providence has provided, middle and late old age have their uses. At any rate the old man is with us and there appears to be no acceptable method of obliterating him, even if it would add to the welfare of the race to do so.

Finding ourselves in this obvious position, it would seem the wise course so to manage that the disheartening effects of years may be as long as possible postponed; and to seek those methods by whose application we may do our utmost to minimize the terrors of senility. If youth is so delectable, let us find how it may be protracted; if old age is so beset with ineptitude, let us not rest until we learn how it may be mitigated. Such a proposal is not quite identical with a scheme for the prolongation of life—mere increase in years, although it would doubtless include this, however, desirable, or regrettable it might be. It has to do directly with something about whose desirability there can be no doubt. In other words, I ask your attention to the question of the practicability of *keeping* the various

1 Oration on Medicine at the Fifty-sixth Annual Session of the American Medical Association, at Portland, Oregon, July 11 to 14, 1905.

functions of the organism, of preserving the physical and intellectual powers, of delaying the onset of degeneration as much as may be, of developing a race less prone to early decay.

Then, besides this, I wish you to consider the feasibility of so managing the senile when once their degeneration has arrived, that many of their miseries may be avoided and the remainder lessened in degree. Having granted that age is inevitable the average man would seem to have become indifferent to his penalty for living, and, if complainingly, he none the less heedlessly allows his forces to ebb away prematurely. With some the whole of existence seems to be spent in infancy, adolescence and senility. There is no period in which one can say, "there is full, healthy maturity." When examined this early senility is found to result from pathologic processes and there the observation ends as though it were conclusive. But the event is not thus to be disposed of, for, according to our best standards, senile changes are always pathologic, and, therefore, the question of prematurity rests on some pathologic reason for cause, or else upon inherent weakness in human vitality. We are in the habit of speaking and thinking of senility as something separate and apart from disease; as a result, not sufficient attention has been given to the question of prevention of age.

On this subject one cannot escape the bold work and bolder thought of Metchnikoff, and I quote at once his description of the degenerations of age: "In senile atrophy the same condition is always present: the atrophy of the higher and specific cells of the tissue and their replacement by hypertrophied connective tissue." It is this same process on which every teacher of medicine constantly harps in discussing disease, the disappearance of the parenchyma and the increase of the stroma.

One need not dwell on the theory of Metchnikoff as to the rôle of the phagocytes in the process; for the moment it is enough to know and recognize that senile atrophy is pathologic and that, essentially, old age is disease. It is unnecessary to discuss the plausible but startling sugestion—that of finding some antiserum which might antagonize the development of the age-producing agencies. Already we possess some knowledge of how to defer age, but this information is not generally insisted on as a guide in living. We frequently allude to measures of prevention, but we do not reduce them to a system which can be taught to the student and to society. If we are further to lengthen the probational study period in medicine, it will be wise to give the matter of deferred old age very careful consideration. If the subject were studied seriously, we would foresee a tremendous improvement in the type of humanity, and the readjustment of many habits, customs, social questions along altogether new lines.

Obviously, real progress cannot be made without accumulating data from which to deduce positive conclusions. At present we lack information on such simple matter as the effect on the organism of diet, exercise, recreation and rest. There are many opinions, but they are largely theoretical. To begin with, we must know something about the material with which we have to deal; that is, the inheritance, the reserve powers, the internal resistance of the individual. In fact, we know very little concerning the inheritance of any one. All are more or less obscure in the matter of family history. There are courts of records in which are found descriptions of estates, but there are no archives in which are deposited accurate descriptions of the various members of the family itself. We are more particular in relation to our domestic animals, especially in the introduction of a new strain. Inquiries are made as to the matter of endurance, longevity, powers of nutrition, good or bad qualities of mind or body, but concerning ourselves, there is an indifference to these important qualities of organic perfection. It would not seem to be altogether impossible to acquire some official record of the physical and intellectual qualities, in other words, strains in men. It is not improbable that if such records were known to exist, they would be not only consulted, but would gradually grow to have an influence on the formation of families. Love is said to know no barriers, but history fails to confirm this view. If a matter of class, of caste, or rank, has been sufficiently important to control the forming of marriage contracts, it is not impossible to conceive of a more intelligent public sentiment which would make an alliance with a family celebrated for physical, intellectual and moral superiority, a thing greatly to be desired; and conversely, which would lead to the abhorrence of an alliance with a family in which freaks, degenerates and incompetents, or in which a tendency toward lowered nutrition, too early maturity, or premature senility were frequent events.

Naturally this is not an affair of a generation, but it is unquestionably a doctrine which ought to be taught. The notion that acquired characteristics can have any transmitted influence on the character of the offspring, as formerly taught by the Lamarckians, is still doing great harm. Our young people should be instructed in the fact that the well being of their posterity depends almost altogether on the native stamina of the germ-plasm with which they are endowed. They should be taught to understand the responsibility implied in maternity and paternity, and should be made to recognize that the greatest influence which they can have on the well-being of their children is in the selection of the sponse. The sentiment should be encouraged that parentage is a matter which concerns the public, and especially posterity, more than it does the parent; that the germ-plasm of the race is of all questions the most important which con-

cerns it. Measures could be adopted which would make it more possible than at present for individuals to inform themselves concerning the family characteristics of the contemplated fiancée. A bureau for the precise registration of disease and causes of death, together with the chief facts in family and personal history, might be established through legal enactments, reinforced and made active by a high social sentiment. Such a bureau would afford the needed information, and the special study of the material thus provided would result in the formation of guiding principles in human biology and race development.

Such a system might seem to be contrary to our laws of personal rights, and, of course, the sanctity of reserve may not be easily disrupted. Nevertheless, with Emerson, "We shall one day see that the most private is the most public energy; that quality atones for quantity," and although we cannot attain at a bound to these heights of wisdom, we may, at least, begin to map out a way. He is short-sighted who supposes that the complacency shown in the devolution of the race must continue, unchanged, eternally. We have only admiring applause for the remarkable accomplishment of Burbank in the vegetable world, and yet such are our deep-rooted prejudices that we shrink from the application of similar principles to human uplifting even when we know it is possible. Shaler remarks that man "sorely needs a herdsman's care." The subject is painful, yet I think it will be acknowledged that susceptibility toward tuberculosis, insanity, alcoholism, epilepsy, *et cetera*, is hereditary. Granting this, it follows that a stock could be developed which practically would be immune to those diseases. Doubtless all will regard the realization of this suggestion to be remote and some may liken it to that of Maeterlinck, who says: "Man may sometime master the secret of gravitation and by means of it steer his planet wherever in the universe he wills." The principle is open to such wide application that it may easily be obscured in absurdity. Nevertheless, here is an honest straightforward truth not so far beyond our reach. It lies in a public demand that none but healthy parents shall be allowed to bear children. The brevity of middle age resides, first, in the inherited quality of the organized tissue; second, in the effects of its environal conditions on each organism. We physicians are making it our function to exterminate disease. Why should we be content with merely pointing out that certain disease tendencies are hereditary without taking some practical steps to prevent such disease. Why should we be content with merely pointing out that certain disease tendencies are hereditary without taking some practical steps to prevent such disease transmission? As an illustration, it doubtless would be a hardship to the syphilitic to make procreation for him a penal offense. Nevertheless, such a course would be full of beneficence to the race. The amount of nervous and other disease in the innocent resulting from syphilis in progenitors is incalculable. The incompetence and misery which often overtake the unfortunate victim in middle life as the result of syphilis, one or two generations removed, must be considered. Those who have studied the subject carefully, regard this disease as responsible for one-fifth of all cases of arteriosclerosis, and of yet a higher proportion in those cases occurring in middle life. A man has not the moral right to beget disease. Notwithstanding that it usually comes through ignorance, it should not be allowed. The profession of medicine should make its convictions bear fruit, and should teach and should be expected to teach that the marriage of a large number of people whose nuptials they now help to celebrate should either be prohibited or else made barren. To those who would regard the realization of these thoughts as unattainable, it may be remarked that the world is yet very young, and as a result, as Carlisle has said, in most things very stupid. At any rate it will be admitted that middle age could be considerably prolonged and the infirmities of old age largely mitigated if we could eliminate from the equation that faulty cell metabolism which arrives through inheritance.

The trend of modern thought is toward the development of the individual. Our researches in therapeutics, dietetics, immunity, gymnastics all alike are directed toward the betterment of the individual by making life possible to many who would otherwise perish, comfortable to many who would otherwise survive in misery—results in prolonging life. Our educational efforts concern themselves more and more with fitting for life the otherwise unfit, in so dealing with the neurotic, the semi-imbecile, the vicious and criminal that they may be practical units in the body politic. The result is that individuals otherwise impossible are so modified that they are finding some happiness in life and become less disturbing elements in society as a whole. There can be no doubt as to the benefit to the individual, and no doubt as to the good which comes from the reflex effect on society. Perhaps nothing counts more for the moral uplifting of the masses than the awakening of personal interest in all altruistic undertakings, but let me repeat, we must dismiss as untenable the views of the Neo-Lamarckians that acquired characteristics of the individual have any appreciable effect on the offspring. It is acknowledged that the natural tendency of defectives of all kinds is toward extermination. Left to themselves, many of these weak strains would disappear. In making it possible for these strains to continue to blend and to dilute the organic type of the race, we are unquestionably lowering the future standard of internal resistance and we are creating a threat to physical, intellectual and moral perfection.

On this subject Professor Woods Hutchinson of this city has said some interesting things.

Is it unchristian or unethical to consider this question from the phylogenic standpoint, or, on the contrary, is it not from the highest ethical plane that we look forward to a means that may elevate man spiritually, strengthen him intellectually, increase his vital and physical vigor, thus widening the period of his usefulness and decreasing his sufferings as a whole? We find ourselves sustained in our efforts when they are directed toward helping the individual, but there seems to be a social veto placed on the study of generic betterment. Weismann and his followers have shown us that the character of the individual depends on the germ-plasm with which he starts life, and although education and favorable environments may modify greatly the individual, they have no effect whatever in improving the character of his posterity. The possibilities of an individual, his resistance to disease, his longevity, his strength and his intelligence are determined beforehand by his inheritance. It is known that it is possible to bring deterioration by introducing an inferior strain. No educational advancement can counteract the injurious effects of this preservation and inbreeding of the bad stock. Unless intelligent foresight be used to prevent this definite and ascertained source of degeneracy, we are likely to find a growing depreciation of our racial stock and, in spite of our modern preventive medicine, a progressive increase of mental and physical disease, and an abbreviation of the working years. By homely methods we have learned that aside from the question of perfect nutrition and proper exercise of function, there is nothing which contributes so unquestionably toward the improvement of organic life as intelligent study of what is known as breeding, in other words by the intelligent blending of the germ-plasm of healthy, resisting, long-lived stock so that there may result not inferior progeny, but offspring superior to the parental stock. I am aware that the question is not new, and that its mere mention exposes one to criticism, not only from the timid and ignorant, but even from the wise and philanthropic, and yet, no one can deny that in shutting our eyes to this truth which Nature spreads plainly before us and which she makes the subject of countless lessons illustrated by individual inferiority, perversity, disease and death, we are not doing all that we ought for the coming race, not all that we might toward assisting that evolution which we hope for, but which lingers so in the process. It will be said that no one can contemplate such a scheme as is here suggested without feeling strongly convinced of its impracticability. Of course, it must be admitted that the large fulfillment of such ideals is at present quite impracticable, but it is not impracticable to study the subject with the hope of finding certain aspects which may admit of modification.

By a study of the subject we would at least offer a reasonable antidote to the possible injurious effects of the modern rage for individualism. More than this, it may be possible, by more or less united action, so to modify established customs, social tendencies and common law that we may elevate the sense of family, and possibly municipal and national morality to a standard high enough to result in our placing the welfare of the community above the desires and the instinct of the individual. As we have somewhat meddlesomely diverted the natural tendency of deterioration and degeneration from its end, thus interfering with the action of the law of the survival of the fittest, it does not seem improper that individualism should recompense society by yielding some of its prerogatives for the welfare of the race; or, to put it more pointedly, it would seem only fair, since we have preserved the life of the weakling, that we should deny him the privilege of paternity, or since we have educated the defective or criminal youth into semi-useful citizenship that we should forbid him the right of increasing the number of his kind. In one of our States a legislative enactment looking toward this end was recently vetoed by the governor who accompanied his decision by a conventional lecture to the profession of medicine on its willingness to disregard the rights of individuals. This illustrates one of the difficulties in the way, and would seem to indicate still another field in which physicians must assume their rôle of public educators. The sentiment of the people is instinctively against public interference with personal privilege. This feeling seems to be particularly strong in the Anglo-Saxon people, and to be contrary to the nature of our institutions; yet, like every other privilege it is susceptible of doing great evil if carried to its full logical extreme.

Are we not as an organic type suffering from an extreme application of individual rights? Are we not inflicting an injury on the race through permitting unwholesome privileges to the individual? Is it necessarily dangerous to attempt to create a public sentiment, a social feeling toward the making of new customs and the enactment of new laws which may result in the elimination of at least some of the more abhorrent and destructive elements that at present are blending with and antagonizing the evolution of the race? Would it not be desirable to have an aristocracy of health? That is to say, to see developed a zeal for physical and intellectual perfection, and to have that zeal supported by public sentiment, so that there might be created something like a caste, the attributes of which should be mental and physical wholesomeness, and from which should be excluded those families which are shown by carefully studied data to come of degenerate or unfit stock? This would result in a contest between the general and the particular. At present the particular, the individual, prevails; in the presence of rightly adapted social feeling

the general would prevail. Evolution would thereby be speeded and not retarded as at present. The principle involved does not seem to be any more unethical than the application of the quarantine laws which now operate injuriously to the individual, but make greatly for the public good.

Let us now consider what may be accomplished in the way of postponing age by the reasonable treatment of even the poor material that comes to us. Undoubtedly the question is as broad as the whole subject of personal hygiene and general therapeutics, and so, for the most part, must be passed; there are, however, some aspects of the subject which deserve special consideration. One of these is the improvement in the nutrition of the aged as the result of good teeth. While all recognize the comfort and convenience which we owe to the dentists, it is doubtful if we fully appreciate how much they have contributed to good health and longevity. For another great advance we have to thank the oculists. Who can estimate the additional resources both of usefulness and happiness secured through the discovery of spectacles and the operation for cataract? Useful eyesight contributes much toward health and long life for the reason that it permits of a continued interest in living which otherwise would be lost. It permits of a struggle for an ideal and in this real happiness consists. The ideal, of course, is never reached, but, as Montaigne says, the reward is not found in the victory, but in the conflict. Perhaps no one factor is so important in maintaining courage and health in old people as the creation and continuance of some keen interest in life, and this interest, even in the otherwise enfeebled, may be kept up by means of useful eyes. Now comes the time worn but neglected subject of arterial disease.

Too often our attention is for the first time attracted to arteriosclerosis by the appearance of fibroid or fatty degeneration, exhibiting itself in the figure, form and viscera of the individual. Even after these later changes appear measures may be adopted to stay the march of the process, but how much better it would be to anticipate it. For instance, by noting the high and rising blood pressure and the physical signs of cardiac strain, by estimating the decline in urinary solids and the rise in the urotoxic unit, by measuring the decline in respiratory capacity, or by detecting the falling off in cutaneous secretion and the loss of the pliability and softness of the skin, we may make ourselves aware that vascular degeneration is progressing. Heedless of these earlier manifestations we shall soon awake to the advent of the state which Sir James Paget has so marvelously described.

In the earlier steps of arteriosclerosis, if intelligent study be given to the individual, to his habits of life, to his excesses and to his deficiencies, very much can be done, and, by thoughtful men, is done, to delay arterial changes and to restore functional activity.

May I trespass so far as to emphasize the importance of judging and correcting the disturbed balance between assimilation and waste —the anabolic and katabolic processes? The facts are so well understood that one hesitates to mention them, and yet just here there is so much neglect of precious opportunity. There are successful methods of lessening the extent of auto-intoxication and of widening the field for the play of nutritional processes. This is so commonplace that we neglect it. Middle age often brings luxury and at the same period the contracting arteries narrow the field of physiologic activities. The circumstances of life and the taste of the man for indulgence in appetite or for excess in undertakings, while the limitations of the organism are increased. The tendencies are thus in opposite directions, and, with Munsterberg we ask, "How can they keep together who are going different ways?" Ultimately, they must separate, of course, but temporarily they may keep company if we help to preserve harmony between them. There is abundant proof that even advanced arteriosclerosis may be so far modified as to delay the oncoming degeneration and to admit of happy usefulness, but the victim must be content with moderation and not hope like Mahomet to cleave the moon in twain.

Advanced arteriosclerosis is too generally neglected, and intoxications of one kind or another are for the most part responsible for it. Our prophylactic and curative measures are readily understood. It is well known that the relatively great fatality of pneumonia and other acute diseases is explained by the greater toxemia which exists late in life. Besides this, the auto-intoxication increases the blood pressure and induces prematurely fatal events of cerebral, cardiac and renal diseases. Almost as deplorable as these are the conditions of unnatural excitement, confusion and depression from which many people unnecessarily suffer in old age. Still further, there may be found in vascular disease the source of much severe pain from which old people suffer. This pain is often referable to the aorta, at times to those forms of aortitis and peri-aortitis of the abdomen recently so well set forth by Teissier of Lyons. The latter has also shown that the pain can be ameliorated, the progress of the disease stayed and even great improvement induced by rational treatment. Aortitis and peri-aortitis often greatly interfere with the flow of blood into the branches of the abdominal aorta, and as a result the organs supplied by these branches suffer special degeneration. In middle age and later life, intractable diseases of the stomach, kidneys and other organs could be dealt with much more successfully, and comfortable longevity secured, if more attention were devoted to this pathology.

There remains for brief consideration the question of what can be done to make old age more tolerable; in other words, to remove it to a physiologic basis. We find on close consider-

ation that most of the derangements from which the aged suffer can be classified as belonging distinctly to pathology, but I am afraid there exists a tendency among us to dismiss these matters as necessary corollaries of senility, without giving them that careful consideration which similar processes receive in younger patients. To a few the diseases of old age have a peculiar charm, and these few who give senile diseases special study seem to agree that the complaints of the aged arise for the most part from toxic causes. Even the threadbare question of arteriosclerosis falls to a large extent under this head. There is good reason for believing that this toxic state which underlies the decadence of senility takes its origin for the most part in the colon. Metchnikoff supports the view that mammals have developed a large colon for the purpose of storing the products of digestion, and that man has inherited a large colon at the expense of his longevity. This organ harbors an immense number of bacteria, leading to fermentations, putrefactions and the production of alkaloids, fatty acids and toxins which man has to combat for the length of his mortal days. While vitality is young and vigorous, the combat is not so unequal, but with failing powers auto-intoxication prevails in the contest between the internal resisting powers of the organism and the toxic adversary made potent by inheritance. Unfortunately the degeneration of age first produces functional insufficiency of the organs of elimination, then their degeneration, and as a result we find the skin, kidneys, lungs, liver incompetent in each individual overtaken by years. It is somewhat remarkable that facts so well understood as these do not receive more attention.

There are few text-books, there is little teaching devoted to the pathology and right management of senile disease, and yet experience teaches that few patients respond more satisfactorily than do the aged if their cases are approached with the principles in mind which are here set forth. It is not merely a question of dilatation of the colon, nor of any special defect of the organ: even in the absence of these, the source of auto-intoxication exists and becomes important because of the failure of the skin and other emunctories which, earlier in life, are relatively sufficient. The indications are obvious. In addition to the usual measures for improving the general circulation, old people are benefited by systematic colonic lavage, stimulating baths with superficial massage, prescribed pulmonary gymnastics and an abundant drinking of pure water. It is the almost universal effect of these matters which has made it seem to me a subject of sufficient importance to call to your attention in a general address. There is something inspiring about youth which gives an incentive to our care of the diseases of childhood and adolescence, but there is something benignant in studying the problems that lead to the postponement of age and to the alleviation of the trials of senility. Old age is repulsive when it is pathologic, but it is beautiful when it is physiologic, and it would appear as a fitting theme for the consideration of this great body at its meeting in this new land of the setting sun.

THE INFLUENCE WHICH THE ACQUISITION OF TROPICAL TERRITORY BY THE UNITED STATES HAS HAD, AND IS LIKELY TO HAVE ON AMERICAN MEDICINE.[1] [2]

BY GEORGE BLUMER, M.D.,
OF SAN FRANCISCO, CAL.

IT is a custom in many universities, both in this country and in Europe to allow each professor leave of absence during every seventh year of service. This custom is doubtless based on the Sabbatical year of the Pentateuchal codes, an institution which demanded that the fields be allowed to lie fallow every seventh year. It is a question whether the Sabbatical year, as an institution, could not with benefit be introduced into matters medical, and whether we might not profit by resting every seventh year, and devoting our time, not to the strenuous throes of medical existence, but to a calm, dispassionate review of the progress of medicine in the preceding septennate, and the factors which have influenced that progress. With this idea in view I have chosen to speak to-day on an aspect of our medical progress which is now in its Sabbatical year.

It is at present almost exactly seven years since, by the terms of treaty following the Spanish War, the United States came into possession of tropical territory in both the eastern and the western hemispheres. It is unnecessary and inappropriate to discuss here the general significance of this territorial acquisition, its bearing on politics, its effect on commerce, its influence on public affairs in general: it is sufficient if we, as the representatives of the medical profession of this country, take stock of the medical questions involved, discuss their significance, and gauge the effect which they exert on American medicine in general. No doubt many of our hyperopic brethren foresaw, seven years ago, some of the effects which our acquisition of Porto Rico and the Philippines was to have on American medicine. There is just as little doubt that some of the results were entirely unlooked for, and have been complete surprises. It might appear at first sight that, from analogy, we should have been able to foretell the influence which increased commerce with our tropical territory, and the return of our soldiers and sailors with tropical diseases, would have on medicine in the United States. Obviously one would look to the experience of European countries, and notably of England, to form a basis for judgment, for these countries have had tropical possessions for generations. It must not be forgotten that

[1] Oration on State Medicine at the Fifty-sixth Annual Session of the American Medical Association, Portland, Oregon, July 11 to 14, 1905.

the physical conditions here are different from those in Europe, for while Europe is almost entirely within the temperate zone, portions of this country are semi-tropic, and a few very small areas are actually within the tropical belt. The United States, therefore, presents a much more favorable soil for the transplantation of tropical diseases than does Europe. Realizing this, numerous American writers on tropical diseases have sounded, in the last seven years, notes of warning and alarm. Their apprehensions are based more on theoretical grounds than on observed facts, but for all that are worthy of our most serious consideration. The object of this inquiry is to determine, if possible, how great this danger is. What are the prevailing diseases of our tropical possessions? Which of them, if any, has appeared among us; which, if any, has gained a foothold on our soil; and which may possibly become widely distributed? Aside from endeavoring to answer these questions, we may with profit glance at the effect which the study of tropical diseases has had on the comprehension of cognate diseases in the United States, and also observe that it has led to the recognition in this country of unsuspected diseases of wide distribution, and great economic importance.

Uncinariasis.—Perhaps one of the most startling results of the increased interest in tropical diseases has been the discovery that large sections of the southern portion of this country are infected with the hookworm, and that large numbers of the inhabitants are suffering from uncinariasis (anchylostomiasis) or hookworm disease. The starting point of this remarkable discovery was, almost certainly, the work of Ashford in Porto Rico in 1900. This observer noted the great frequency of the disease in that island, and pointed out that, to a large extent, the disability and wretched condition of many of the natives was due to it. The credit for drawing attention to the probability that the disease was widespread in our Southern States is due to Charles Wardell Stiles, the Zoologist of the Bureau of Animal Industry, and to him also is due the credit of amply proving what he at first brought forward merely as a probability. It would be out of place here to go into detail as to the clinical history of this disease, or the minute structure of the parasite which causes it. Mention must be made, however, of Stiles' discovery that the American uncinaria differs from that of Europe. It will be of interest to consider the geographical distribution of uncinariasis in this country, the main facts connected with the method of its spread, and the evidence as to the likelihood that it will become more widely prevalent than it is at present.

Up to the year 1900 not more than ten authentic cases of uncinariasis were on record in American literature, though there are statements by Southern physicians in the writings of the early part of the nineteenth century which leave little doubt that the disease was then prevalent. During 1900 and 1901 only nineteen cases of the disease were reported, but in 1902, following the publication of Stiles' monograph on "The Significance of the Recent American Cases of Hookworm Disease in Man," the number of reported cases rose at a bound to 524. In 1903, 273 cases were reported; in 1904, 334; the number this year will probably not be so large, as the disease is no longer a rarity to Southern physicians, and they will not be so apt to record cases. Prior to 1900, then, possibly ten authentic cases of hookworm disease had been reported; since this date I have been able to collect from the available American literature 1,212 cases, of which 1,095 originated in the United States, and 117 were imported from other countries, mainly from Porto Rico and the Philippines. Of the latter 62 are reported by Gunn, and occurred in San Francisco, mainly among Porto Ricans.

If we separate the domestic from the imported cases we find that this disease is distributed mainly through the Southern States along the seaboard from Virginia to Texas. But it is not confined to seaboard States, for Missouri and Tennessee are also infected. The States in which the disease is known to be indigenous, and probably widely distributed, are Virginia, North and South Carolina, Georgia, Alabama, Florida, Louisiana, Texas, Mississippi, Missouri and Tennessee. This list of States includes only those in which definite evidence of the presence of the disease has been furnished; it does not include, I think, all of the infected States. Taking into account the similarities of soil and climate, anyone who will take the trouble to make a map of the known infected area will feel convinced that Arkansas, Indian Territory, Oklahoma, West Virginia, Kentucky, and the southern portions of Illinois, Indiana and Ohio are also probably infected. The physicians in some States have shown a lamentable lack of enterprise in investigating this disease, while in other States extensive and valuable studies have been made of it. As I have already stated 1,095 cases of domestic uncinariasis have been reported since 1900; 824 of these have been observed in three States, Georgia, Alabama, and North Carolina. This has been due to the interest and energy of single physicians, in Georgia of Claude A. Smith, Warfield and Harris; in Alabama of E. D. Bondurant, and in North Carolina of Nicholson and Rankin. A knowledge of the distribution of the disease is not merely of academic importance, for the economic aspects of uncinariasis are paramount. There is little doubt that the stigma of laziness and general inefficiency which has attached for generations to the so-called "poor whites" of the South has been earned by them not as a result of qualities due to innate "cussedness," but because a large percentage are suffering from uncinariasis with the resultant physical and mental deterioration. This being the case, a plotting out of the infected areas is one of the first steps which must be taken preparatory to

stamping out the disease. This is only one step, however, the others depending on our present conception of its method of spread. At present there are two main theories as to the means by which the parasite gains entrance to the body, the one presupposing that it enters through the alimentary canal, the other that it gains entrance through the skin. The advocates of the former theory hold that polluted drinking water, and food soiled by dirty hands are the means of introduction, the advocates of the latter, that the so-called "ground itch" is the point of entrance of the *Uncinaria rhabditcs*. There is a good deal of evidence in support of both views, though the work of Claude A. Smith and of Nicholson and Rankin favors the idea that the cutaneous form of infection is the more important. In view of this the wearing of shoes, especially during the rainy season, becomes the most important prophylactic measure, though the necessity for pure water supplies and the proper disposal of excreta still remains of great importance. In all such matters the enforcement of hygienic laws can never be obtained without education of those who are at fault. As uncinariasis is essentially a country disease (I have not been able to find on record a single American case which originated in a city), the question is one which must be dealt with by the country physician, on whose back falls a heavy load of responsibility. The stamping out of this disease is, of course, of great economic importance to the South, but, further than this, the question arises whether it may not be of importance to other parts of the country. Is there any chance that uncinariasis may become more widely distributed than it is at present? The question is a hard one to answer. While there has not been a lack of physicians who have predicted such a spread, it cannot be said that there is much actual evidence that it has occurred. There are a few instances in American literature in which the evidence plainly points to infection of natives from imported cases. Such, for example, are some of the cases reported by Möhlau in Buffalo, where Polish and Italian laborers contaminated a brickyard. That such sporadic outbreaks can and will occur cannot be denied, and physicians all over the country should be on the lookout for them. Whether the disease will ever become widespread outside of its present habitat is quite another story. It must not be overlooked that a variety of circumstances are necessary to its spread; the right kind of soil, sufficient heat, and enough moisture for the parasite, and a lack of certain hygienic precautions on the part of the inhabitants of the area to be infected. The absence of any one of these conditions may be fatal to the dissemination of the disease. Considering the fact that uncinariasis has existed in the South for at least 100 years, and probably longer, it does not seem very probable that it will ever extend much beyond its present limits. What is needed at present then, is a more accurate knowledge of its distribution, and the inauguration of an educational and sanitary campaign to effect its extermination.

Dysentery.—One of the first diseases which the American army surgeons in the tropics had to confront was that scourge of camps, dysentery. The study of the acute form of the disease had received a great impetus from the work of Shiga in Japan, and the investigation of this condition in the American troops in the Philippines, instigated by Flexner, has since been carried on by Strong and Musgrave, J. J. Curry, and Charles H. Craig. It can fairly be said, I think, that our conception of the etiology of dysentery, and particularly of the tropical form, has been completely revised in the last few years, and this revision has depended, in no small measure, on the work of American investigators. So far as tropical dysentery is concerned, the studies of recent years have taught us to recognize two distinct forms, the bacillary and the amebic. The bacillary form, of which the acute dysentery of the tropics represents the most common type, is due to an organism first described by Flexner, and closely allied to the bacillus described by Shiga in the epidemic dysentery of Japan. In the chronic forms the ameba seems to have held its ground as the main causal agent, though the earlier investigators in the Philippines seemed inclined to think that it was usually a secondary invader. Our knowledge of the life cycle of the ameba, of the differentiation of pathogenic from non-pathogenic forms, and of the cultivation of the organism, has been achieved in the past few years, and is associated with the names of Craig, Strong and Musgrave, and Caspar Miller. A more exact knowledge of the complications of dysentery has also resulted from the work of our army surgeons, and it is to be especially noted in this connection that the so-called "tropical" abscess of the liver is nearly always due to the amebic as opposed to the bacillary form.

The most surprising and unlooked-for result of the stimulus given to the study of dysentery has been the discovery that the same group of organisms which are responsible for tropical bacillary dysentery are also concerned in dysentery in this country, and in certain forms of the summer diarrheas of infancy. The first steps in determining these relationships were taken under Flexner's guidance during 1902. In that year Vedder and Duval published the result of their work on the dysentery of the United States, work which was based on both sporadic and epidemic cases, and which showed that certain types of dysentery all over the world were due to the Shiga group of bacteria. In the same year Duval and Bassett published their preliminary announcement of the isolation of bacteria of the same group from cases of infantile summer diarrhea. Subsequent studies, conducted mainly at the large centers in the East, have, in the main, confirmed these observations,

and have led to more accurate knowledge of both the clinical and bacteriologic aspects of these two classes of disease. Since 1903 investigation has been mainly focussed on the summer diarrheas of infancy, the scourge of the tenement districts of the large cities. These studies have resulted in the classification of the *Bacillus dysenteriae* into three main types, a differentation which was suggested in part by Gay and Duval in 1903, and which has since been rendered more exact by the work of Hiss and Russell, and that of W. H. Park and his associates. On the clinical side it has been shown that all classes of summer diarrhea are not due to organisms of the dysentery group, but that certain types associated with mucus and blood in the stools are nearly always associated with them. It has also been shown that these organisms, like the pus cocci, may give rise to primary infections, or may play the rôle of secondary or terminal invaders. Mild cases without blood in the stools may also be due to this group of organisms, accurate and early diagnosis only being possible in any type of case by means of a bacteriologic examination of the feces. The serum reaction, while of some value, appears late in many cases, and is not available for early recognition of the disease.

In his report on Philippine dysentery Flexner suggested the possibility of serum therapy in these cases, and the discovery of the relation of the *Bacillus dysenteriae* to infantile summer diarrhea led to attempts at the production of a curative serum. During 1904 such a serum was used in a number of outbreaks of dysentery and summer diarrhea. The results, as a whole, have been disappointing, and will probably improve as we gain in experience. As Booker pointed out in 1903, little is to be expected from the serum in cases in which marked anatomic lesions are present. The work done under the Rockefeller Institute and summarized by Holt shows that the serum to be of value must be used early and in repeated doses. Judging from the results of Shiga in Japan more is to be expected for the serum treatment, and, as a matter of fact, it has not yet received a fair trial in this country. At present we need more knowledge regarding the natural history of the dysentery germ, its method of introduction, and the distribution of this form of infection in the United States. As regards the means by which the germ is introduced into the body there is already some evidence, both from the Philippines and this country, that contaminated water is at fault, but the whole matter needs more thorough investigation. The distribution of this form of infection has hardly been studied outside of the large cities of the East, and although the severe forms of infantile diarrhea are almost unknown on the Pacific Coast, there is little doubt that they exist in the South and Middle West.

Yellow Fever.—At the time that the Island of Cuba was occupied by American troops in 1898, yellow fever had been endemic there for 130 years. The disease was not widespread, but was mainly confined to the coast towns, and was particularly prevalent in Havana, the continuous stream of non-immune Spanish immigrants serving to keep up the infection. A great deal of study had been devoted to the disease at this time, and in the years immediately preceding the Spanish war renewed interest had been awakened by the work of Sanarelli, who claimed to have found the causal agent in his *Bacillus icteroides*. His claims had met a good deal of opposition, especially from Sternberg in this country, and many yellow fever experts did not accept his results. In view of the prevalence of the disease, and the constant menace which it offered to our Southern States, a commission composed of Walter Reed, James Carroll, Jesse W. Lazear, and Aristides Agramonte was detailed to Cuba still further to study it. The commission presumably started out with a disbelief in Sanarelli's work, for certain of the members had published investigations showing that the *Bacillus icteroides* was closely allied to, if not identical with, the hog cholera bacillus. While Sanarelli's work was repeated as a necessary precaution, and was proved to be erroneous, the commission concentrated its efforts on the investigation of the relation of the mosquito to yellow fever, a relationship which had been insisted on by Carlos Finlay, of Havana, for nearly twenty years, and which the work of Carter on the time limit between primary and secondary cases rendered probable.

It is not necessary to go into details as to the methods used by the commission in their work, further than to state that they were scientifically above reproach. It will be of interest, however, to consider their results, and the influence which they have had on the practical aspects of yellow fever quarantine. Briefly stated these results were as follows: The proof that Finlay's conception that yellow fever is conveyed by a certain variety of mosquito (*Stegomyia fasciata* of Theobald) is correct. The demonstration that a certain time must elapse after the mosquito is infected before it can transmit the disease; that the causal agent is in the blood during the first few days of the disease, that it can be destroyed by heat, and that it can pass through filters which hold back some of the smaller forms of bacteria. The explosion of the old idea that the disease can be conveyed by fomites, unless these are of a character to allow of transmission in them of infected living mosquitoes. These are the main results, and they have led to greater accuracy in our knowledge of the incubation period of yellow fever, increased study of the yellow fever mosquito, and an entirely new conception of the prevention of the disease. Since the original work of Reed, Carroll, Lazear, and Agramonte several independent observers have confirmed their findings, notably Guiteras in Cuba, Marchoux, Salembini, and Simonds in South America, and the working parties of the

U. S. Public Health and Marine-Hospital Service in Vera Cruz, Mexico. The investigations carried on under the Public Health and Marine-Hospital Service have also supplied many details extending our knowledge of mosquito transmission, of the life history of the yellow fever mosquito, and of quarantine methods against the disease. Few discoveries in medicine have led to more rapid and more brilliant practical results that those above cited. The story of the remarkable change in the yellow fever history of Havana achieved by the work of Gorgas reads almost like a romance. When we consider that the annual number of deaths from yellow fever in Havana for the ten years preceding the establishment of the mosquito theory averaged about 500, and that under Dr. Gorgas' administration they were cut down in two years to nothing, we can enthusiastically echo the sentiments expressed in a resolution of the conference of State and Provincial Boards of Health, in which they say: "We regard (it) as one of the most brilliant achievements of the application of sanitary science to public health work ever accomplished." Judging from recent reports it seems likely that Gorgas will repeat his Havana success in the Isthmian Canal zone. We have still to discover the cause of yellow fever, and we have still to ward off its advances in our Southern States. So long as our Central and South American neighbors pursue their present lax sanitary methods we are liable to have sporadic outbreaks of the disease in those regions in which the *Stegomyia fasciata* can multiply. As Carter and Howard have shown, this mosquito is widely distributed in the subtropic portions of our country, and it behooves us to continue with the work of mosquito extermination, to increase its range as rapidly as possible, and to keep up with its oldtime strictness and quarantine vessels, especially sailing vessels, from infected ports. The protection of our land boundaries to the South will, of necessity, be much more difficult, and judging from the recent experience in Texas, it is by this route that infection is now most likely to reach us.

Malaria.—The soldiers returned from Cuba and Porto Rico, and later those from the Philippines, offered an opportunity for the study on a wholesale scale of certain aspects of malaria, an opportunity which was grasped by both military and civilian physicians. During and immediately following the Spanish War the accomplishment of greatest importance resulting from this study was the overthrow of the refuge of the careless diagnostician, typho-malarial fever. Those physicians who had studied malaria and typhoid fever carefully before the war, and who had controlled their diagnoses by blood examinations, had always been skeptical about the existence of combinations of the two diseases, and had published from time to time protests against the indiscriminate use of the term typho-malarial fever. It needed the studies of the camp fevers, however, to prove to the satisfaction of most physicians that the combination was exceedingly uncommon, and that when it occurred the malarial fever preceded, or more commonly, followed the typhoid fever. In his remarks on the subject, based on the examination of the blood of 159 typhoid cases at Camp Wikoff, Ewing says: "In no case of undoubted and established typhoid fever were malarial parasites found in the blood in connection with any of these sudden rises of temperature (in typhoid), but only at the onset of the disease or during convalescence," and later in his article, "In short, in spite of painstaking effort, the attempt to find a case of typhoid fever and active malaria progressing simultaneously was unsuccessful." Aside from this, the clinical study of the disease has received but few important additions since 1898, though mention must be made of the valuable studies of Craig on latent and masked malaria, studies which showed how great the danger to a community might be from soldiers returned from the tropics. In his article published in 1904 Craig states that 25 per cent. of the soldiers returning from the Philippines show latent or masked infections, and in a large percentage of these cases the parasite is the estivo-autumnal crescent, a stage of the organism capable of development in the mosquito. The same observer cites one company of 60 men in which 41 had parasites in their blood, and yet but 14 complained of illness.

As far as the parasitology of malaria is concerned, the past seven years have been marked by great simplification in staining methods, but discoveries of paramount importance have not been numerous. The studies of Craig on estivo-autumnal fever have tended to confirm the views of the Italian school as to the duality of its parasite, and the work of Ewing on the tertian parasite has thrown light on its early sexual history in the circulating blood. Working Party No. 2 of the Yellow Fever Institute has been able to show that at the time of the malarial chill there is present in the blood a toxin, and have been able to produce a chill by the intravenous inoculation of filtered blood extracted during the paroxysm.

The study of the distribution of the malarial mosquito has been carried on in a few places, in Boston by Theobald Smith, in the Valley of the Androscoggin by Jordan, and in Baltimore by Hirshberg and Dohme, but the amount of work which has been accomplished in this direction, and the time and money which have been expended in the attempt to exterminate the malarial mosquito, is almost infinitesimal when we consider the territory affected by the disease, and the losses resulting from it. Woldert estimates the annual financial loss in Texas alone at over $5,000,000, and if all the infected zones in the United States are considered the loss must be appalling. Like yellow fever, malaria is a perfectly preventable disease, but to stamp it

out requires either destruction of malarial mosquitoes, or protection and sterilization of infected individuals. In this country mosquito extermination has always been the favored plan, but before it can be accomplished a much more complete knowledge of the distribution of the *Anopheles* is necessary, and much more thorough education of the public as to the necessity of the work. The danger that the disease may be introduced into uninfected areas by soldiers returning from the tropics is a real one, though, as Theobald Smith has shown, it is unlikely that the estivo-autumnal parasite will be introduced into the Northern States. Still, we have plenty of Southern territory not yet infected, and the extermination of mosquitoes would prevent the possibility of such contamination. The question is one which has not yet been seriously considered in large sections of the country, but is, nevertheless, of the greatest importance.

Filariasis.—The work of Ashford in Porto Rico, and of Calvert in the Philippines has shown that filariasis exists in both places. In Porto Rico it is probably widely distributed, as Ashford found it in 30 out of 250 soldiers in the Porto Rican regiment. Cases of Gunn and of Brown have shown that infected individuals from this source have already reached this country. In the Philippines the extent of the disease is doubtful. Calvert found the filaria in only two out of 426 Filipinos, but it is to be noted that both of these individuals came from the same district, and it is likely that the disease is much more prevalent in some places than in others. In this country several domestic and imported cases have been reported since 1898. It seems extremely likely that the disease is much more common in the South than the literature would indicate, and that it is often overlooked. The fact that one man, De Sassure, of Charleston, was able to report 22 cases, most of them originating in the United States, is pretty strong evidence that the disease is much more prevalent than is generally supposed. It is certain that there are present in this country varieties of mosquito capable of transmitting the filaria. As these generally belong to the *Culex* family, which is widely distributed throughout the United States, it seems possible that there is real danger of new districts becoming infected by returning soldiers or Porto Rican laborers. Before the matter can be definitely settled we need more information as to the exact varieties of mosquito which can transmit filariasis, and their distribution in this country. At present it is quite generally assumed that a number of varieties of *Culex*, and at least one of *Anopheles* can transmit the disease. We believe it was Myers who brought forward evidence to the contrary, and the matter is one which needs further investigation.

Malta Fever.—The fact that Malta fever was present in Porto Rico was first demonstrated by Musser and Sailer, and later by Cox and Curry. In 1900 Strong and Musgrave called attention to its occurrence in the Philippines, and still later cases occurring in returned soldiers were described by Curry and Craig. The number of cases which have been described is small, and practically all of them are in soldiers and sailors. In the seven years which have elapsed since the first case was reported in this country, no case originating here has been described, and it seems that there is little likelihood of the disease becoming disseminated in the United States. It is within the bounds of possibility, as Curry pointed out, that it already exists in the Southern States. In its acute form it is easily confounded with malaria, and in its chronic stages it is generally diagnosed at first as chronic rheumatism. The serum reaction of the disease is so reliable, and the test is easy of performance, that all cases with doubtful fevers in the Southern States should be subjected to it. It seems highly probable that if this is done systematically the disease will be found to be present.

Trypanosomiasis.—The relation of trypanosomes to animal diseases was observed in the middle of the last century, and renewed interest has been awakened in these parasites in recent years by the discovery of new forms of animal trypanosomiasis initiated by the work of Dutton. The presence of the trypanosome infection known as surra among horses and buffalo in the Philippines was noted soon after the American occupation, and the results of American researches on this disease may be found in the valuable monograph of Musgrave and Clegg. Up to 1903 attempts to isolate trypanosomes in pure culture had been ineffectual, but in that year McNeal and Novy published the results of their work on the rat trypanosome. They were able to obtain the first successful pure culture of a pathogenic animal parasite with the absolute demonstration of its causal relation to the disease. Up to this time many observers believed that the different forms of animal trypanosomiasis were due to the same organism, but during 1903 and 1904, Novy, McNeal and Ward were able to cultivate the trypanosome of nagana or tsetse disease, and also that of Philippine surra, and could demonstrate that the parasites from these different diseases showed variations in structure and mode of growth. Later Lewis and Williams succeeded in cultivating the frog trypanosome, showing that this also differs from the other forms. Some forms of animal trypanosomiasis have appared in the United States, dourine having been observed in Nebraska. Whether there is any possibility of the introduction into America of human trypanosomiasis will be difficult to determine until we know more of certain forms parasitic in man, and the method of their spread. The form of the disease which is most likely to appear in this country, is the affection known likely to be found in the Philippines, and hence most in India as kala-azar or dum-dum fever. The parasite of this disease, usually spoken of as Leish-

man-Donovan body, has recently been shown by Rogers and Chatterjee to belong to a subfamily of the trypanosomes. The method of transmission of this form of the disease to man is not definitely known so far as we can determine; it is probably transmitted like nagana by an insect, most likely a mosquito. The possibility of its introduction into this country will probably depend on the presence or absence of some insect host.

Dengue.—A disease which does not seem to have received the study which it merits, considering its frequency, is dengue, or break-bone fever. The Reports of the Surgeon General of the Army for 1902 and 1903 show that in the Philippines it caused, in the former year, 31.67 cases of sickness per 1,000 of strength, and in the latter year 171.39 cases per 1,000 of strength. Presumably it has not been carefully studied in the Philippines, or in the South, where it also occurs, on account of its short duration, and the almost absolute lack of fatalities. In the Isthmian Canal Zone it has been studied in the last two years by Sutton and Carpenter. They have shown that it is probably not of the malarial class of diseases, but that it may, as Graham claimed, be transmitted by the mosquito. Their studies of the blood show that it is one of the diseases accompanied by leucopenia and relative lymphocytosis, and their bacteriologic studies suggest that a bacillus similar to the influenza bacillus may be the cause. The disease is one which, judging by its history, is unlikely to spread beyond the southern parts of this country. It is worthy of more extended study by modern methods than has yet been devoted to it, and American physicians in the Philippines and the Isthmian Canal Zone will probably have excellent opportunities to clear up many moot points in connection with this disease.

Asiatic Cholera.—During 1902 Asiatic cholera appeared in Manila, spread to the neighboring islands, and caused over 90,000 deaths before it was stamped out. The incidence of the disease among the whites was comparatively small, but among the natives it ran rife, owing to their lack of hygienic precautions and the favorable temperature conditions. In many instances the disease was not carried, as usual, by contaminated water, in fact, in the large cities indirect contact through food was a much more frequent method of spread. On account of the violent local reaction produced by Haffkine's cholera prophylactic the natives objected to its use, and as the scattered distribution of the population made it almost impossible to control them, this method was given up. The objections to Haffkine's prophylactic lead R. P. Strong to attempt the production of a protective serum lacking in the irritating properties of those hitherto used. By a process of bacterial autolysis followed by filtration of the culture he was able to produce a practically non-irritating protective. From the experimental standpoint Strong was able to show that animals and men treated by this method showed but little local reaction, yet developed in their blood substances strongly bacterial to the cholera spirillum. As the cholera had practically disappeared from the Philippines at the time that Strong's work was completed there has as yet been no opportunity to put his method to a practical test. From what we know of the disease there is little likelihood that it will ever get a foothold in this country under our present quarantine regulations.

Plague.—The appearance of plague in several parts of the civilized world in 1900, and especially its appearance in San Francisco and Philippines, called the attention of American medical men to this disease. Luckily, but few of them had an opportunity to study it, and most of the American work on this disease has been done in the Philippines, where, according to Munson, 970 cases with 812 deaths occurred between January, 1900, and September, 1903. It cannot be said that anything startlingly new was discovered during this period, but a good deal of valuable confirmatory work was turned out. In this connection must be mentioned the work of Barker, Flexner and Novy on various aspects of the subject, the work of Calvert and Ewing on the occurrence of plague bacilli in the circulating blood, and the work of Herzog and Hare on latent and ambulatory plague. The outbreaks of the disease in Australia, in Honolulu, in Glasgow, and in San Francisco have served to warn us of the necessity of being constantly on guard against its insidious approach. The recent outbreak in Leith, in which, as in the San Francisco outbreak, the origin of the disease was in doubt, shows us that at all our seaports constant vigilance must be maintained, and this must be the case so long as endemic foci are present in Asia. In the preventive work in this country, in this as in other infectious diseases, too much praise cannot be given to the officials of the U. S. Public Health and Marine-Hospital Service who, besides having to bear the burden of their appointed work, have often also to suffer the slings and arrows of outrageous politicians, and the contumelious taunts of misguided citizens.

Conclusion.—We have now considered the more important of the tropical diseases which occur in Porto Rico, the Philippines, and the newly acquired Isthmian Canal Zone, the effects which their study has had on American medicine, and the chances of their becoming domiciled in this country. It has been possible to touch on many important subjects but lightly, and I ask your indulgence for the sketchy manner in which the subject has been treated. Of necessity a number of tropical diseases have not been mentioned, tropical ulcer, frambesia, bilharziasis, and blackwater fever, for example. These diseases are all present in our tropical possessions, but are of relatively minor importance, and as yet have received but little attention from American observers. Two general conclusions are forced on

us as a result of this study, one being that many of the so-called "tropical" diseases are widely scattered through the subtropical portions of this country, the other that the acquisition of tropical possessions by the United States has had a markedly stimulating effect on American medicine, and has led to valuable work, some of it of the very first rank, all of it showing evidences of earnest and painstaking effort.

THE TREATMENT OF DIARRHEA IN CHILDREN.[1]

BY JOSEPH E. WINTERS, M.D.,
OF NEW YORK;
PROFESSOR OF DISEASES OF CHILDREN, CORNELL UNIVERSITY MEDICAL COLLEGE.

Lack of precision in terms is the root of confusion in treatment.

Dysentery, an infectious, contagious, epidemic, water-borne disease; characterized by tormina and tenesmus, and by blood and pus in the stools, is not included.

Diarrhea with blood and mucus in the stools is often erroneously denominated dysentery. By no process of extension, transition or evolution does diarrhea ever become dysentery, as is now authoritatively stated, with no credible basis. For dysentery there must be specific infection—a specific micro-organism.

If a child with diarrhea contracts dysentery, there are two entirely distinct, coexisting diseases in one patient; they are as distinct as they would be if they occurred in two patients.

This definitive elimination clears the decks for *decisive, direct* therapeutic action.

During seventeen summer weeks in 1903, Brooklyn and Manhattan had 2,755 deaths from diarrhea; during the same period in 1904, 3,810 deaths. A notably cool, salubrious summer, registered a death-roll from a minor affection, which not only unsettles and staggers the practitioner, but also casts a shadow across our science.

Mr. President, this is an effaceable mortality column.

Diarrhea is purely a food disorder. Therefore, preventable. At inception, prompt, appropriate treatment, unfailingly arrests it at once. Therefore, it should never be fatal. It registers more deaths than all the contagious exanthemata combined. Mismanagement of feeding is the cause.

In young infants, barley water, rice-water, egg water, etc.; in older children, animal broths, continued until vitality is at such an ebb that there is fatal collapse, have produced a mortality record from a simple local irritation, which is not only infamous, but iniquitous.

The marvel of this complaint is the simplicity of successful management, viz., removal of the cause, feeding adapted to the condition.

1 Read before the New York County Medical Society at the New York Academy of Medicine, May 22, 1905.

Removal of Cause.—Fermenting food (soon putrescent), a lurking menace, must be ejected promptly, radically, entirely, to prevent a mere local affection becoming a profound constitutional infection, *through the great activity of the intestinal absorbents.*

Difficulty of Removal of Cause.—Numerous transverse folds in the intestine, two inches in length, two-thirds of an inch in depth (for impending propulsion of food and expanding absorbent area), make it difficult to dislodge and drive out the putrefying, irritating material.

The instrument of eviction must be as searching, as scouring, and as potent as a chimney sweep or a scavenger.

The cause, milk curd, sour milk, unripe or overripe fruit, fruit skins, bolted boluses, morsels of sweets, sausage, cheese, cabbage, sauerkraut, etc. (entrapped under, concealed and shielded by an intestinal food—*enhance physiological, accentuate pathological processes*); the cause thrust out, the irritated parts must have a period of rest—unconditional, absolute, motor and chemical.

Being the food-path does not debar literal observance of this first therapeutic law—punctiliously enjoined, jealously, religiously enforced, as in other irritated and inflamed structures.

Rest must be assured, unquestioned because unquestionable, until fermentation ceases, and the injured and irritated mucous membrane at all points and in all valvular pockets has healed.

It is prerequisite, therefore, during this transition stage, or period of probation, that nothing be allowed to pass through the digestive tube but water.

While there remains any trace (cause or consequence) of the original disturbance, food is as a spark in a powder magazine. In this functionless state the blandest nutriment eternizes fermentation. Escape from mortal issue is cut off. Feeding while disorder lingers is fatal error.

The only adequately exploring, extruding agent is castor oil.

To a child of three months and of six months, one teaspoonful; to a child of nine months and of one year, a desertspoonful; to a child of one year and a half and of two years, one tablespoonful. The oil must be ice cold.

For two hours before and two hours after, nothing else must go into the stomach—not even water. If the oil is rejected the same dose must be repeated in one hour.

Not infrequently an irritating mass is incarcerated in a valvular pocket. To abate spasm and liberate this, opium is indispensable—a solid, hardened dejection then passing downward carries with it the released material. Opium has obviated sepsis!

The only legitimate use of opium in diarrhea, is for the surrender of imprisoned, decomposing, septic material. If this remains, the issue is fatal.

After the detergent, cleansing, purifying action of the oil has *ended*, for at least another twenty-four hours only water is to be given. In severer cases thirty-six, forty-eight, sixty, or even seventy-two hours must elapse before the maimed intestine can be safely intrusted to perform any digestive function. Feeding while disorder lingers is fatal error.

In young infants hot water, and from a bottle, is preferable. Where there is great irritability of the stomach hot water is more soothing than cold. Some infants, and most older children prefer cold water. Heed preference. When there is high temperature cold water is grateful and of therapeutic value. Very hot water from a dropper, three or five drops on the tongue every fifteen minutes, is at times magical in its effect in checking vomiting.

The rest and restoration period over, the pivotal part of the management begins, namely, feeding. The food must be a modified and weakened form of that which is physiological for a well child of the same age. Unphysiological feeding is unmitigated egotism. He is indeed a hopeless pigmy who places his fallible opinions and conclusions above Nature's infallible laws!

To give barley water and dextrinized cereal to a young infant in health or disease, is such express contravention of physiology as to be stultifying.

This incomprehensible blunder has lowered the colors; shattered faith which should be unbound, unassailable.

Feeding.—Proteid excess is the eminent peril of the young child in summer; it is pre-eminently of evil repute when digestion is disordered or enfeebled. Proteid excess has placed an unwarrantable, an utterly indefensible ban on milk feeding in diarrhea; foisted in the proprietary banes; the illogical, inane and pernicious dextrinized cereals.

After clarifying with oil, flushing and sweetening with water, milk, with the proteid content minimized temporarily, later strengthened under clear insight, is the only sure, safe, ever unfailing resource in diarrhea in a child under one year.

The auspicious moment for food having arrived, written instructions—never verbal—are to be placed in the hands of the child's attendant.

Feeding a Child of Three Months with Diarrhea.—Take the *upper one* ounce of cream from a quart bottle of milk which has been standing on ice for sixteen hours from the time of milking. (Immediately after milking, the milk must be put in the regulation quart glass milk jars of commerce, and placed on ice for sixteen hours before lifting the cream.) In metropolitan centers the milk bottles must be kept on ice for six hours after they are delivered in the morning by the milkman. It is not possible to secure the top ounce of cream by any device other than with the keel-shaped dipper of the Noël Nursery Table.

This one ounce of cream must be kept on ice until it is to be used. Mix one teaspoonful of this cream with one ounce of cold, unboiled, filtered water, and then add two teaspoonfuls of lime water. Of this mixture give one ounce every four hours.

Midway between each feeding, the baby is to be given water from a bottle, hot or cold according to taste, one or two ounces as desired (food and water alternating every two hours). Filtered unboiled water is always to be used. This feeding is to be continued for at least twenty-four hours.

If at the end of twenty-four hours of such feeding there is evidence of intestinal fermentation, the same feeding is to be continued for another twenty-four hours. If, however, at the end of the first twenty-four hours of this feeding the child is doing well, with no indication of disturbance of digestion, the one ounce of food prepared as above is given every two hours, and the water discontinued.

It is of great importance to bear in mind that digestion is not *only* a chemical, but a mechanical act as well. *Not one drop of water is ever absorbed from the stomach*, therefore, when water is put into the stomach there must be the same amount of muscular contraction as for food, in order to force it into the intestine where it is absorbed.

This mechanical act alone may cause exhaustion of the nervous centers. Many well children are made ill by giving water too frequently; many ill children are kept from recovery by the same mismanagement. Frequent muscular contraction of the stomach from water too frequently given causes atony of the stomach and inability to carry on digestive processes.

At the end of the second twenty-four hours of feeding at two-hour-intervals, of one ounce of the above composition, if the child is perfectly well, and evidently not satisfied—as it probably will not be, the quantity but not the strength, is to be increased. Now give 1½ ounces every two hours.

At the end of another twenty-four hours, if digestion is good, the strength is increased. Here lies the most important point in the management. Continue to use the upper one ounce of cream from the top of a quart bottle of milk, and in order to get sufficient quantity for the twenty-four hours' use, take the top ounce from two, or possibly three quart bottles of milk, that a minimized proteid food may be secured.

Use two teaspoonfuls of this cream to 1½ ounces of cold, unboiled, filtered water, and to this add one-half ounce of lime water. Of this stronger food give two ounces every three hours.

After two days of this feeding, if the patient is in every way doing well, the food may be strengthened by taking the upper two ounces from one, two, or three quart bottles of milk sixteen or more hours after milking. Of this, use at each feeding one-half ounce, mixed with two ounces of cold, unboiled, filtered water, and

add to this one-half ounce of lime water. Give three ounces of this every three hours, seven feedings in the twenty-four hours.

From this time the changes are made very gradually until the food is of normal strength for a child of three months. It must be borne in mind, however, that after even a slight intestinal disturbance, the predisposition to enfeebled digestion remains until the end of the summer period. The food must be of *low proteid* until the cool autumn weather.

Feeding a Child Six Months of Age with Diarrhea.—Take the upper *one* ounce of cream from each of *two* quart bottles of milk sixteen or more hours after milking. Of this cream use *two teaspoonfuls* mixed with 1½ ounces of cold, unboiled, filtered water, and then add three teaspoonfuls of lime water. Give a six-months-old child 1½ ounces of this food every four hours, alternatively with 1½ to 2 ounces of water every four hours.

This older child will probably require a larger amount of liquid, and consequently it will be necessary to give a larger quantity of water every four hours. A six-months-old child with better muscular development, may take with impunity a larger quantity of water than a three-months-old child.

At the end of twenty-four hours of this feeding, if all evidence of disturbed digestion has disappeared, prepare the food as follows: Take one-half of the upper *one* ounce of cream, mix this with three ounces of cold, unboiled, filtered water; to this add one-half ounce of lime water. Give three ounces of this every three hours, the water which has previously been given to be discontinued. If the three ounces do not satisfy, and the baby must have more liquid, water should be given immediately after feeding, but not between feedings. Water must not be given in the intervals of the three hours. This would keep up continuous muscular contraction and again lead to exhaustion. There must be a rest-period of three hours.

This régime should continue for about forty-eight hours, when the food may be strengthened by taking the upper two ounces from each of three quart bottles of milk sixteen or more hours after milking, or in town six hours after it is delivered in the morning by the milkman.

Of this two ounces, use for each feeding one ounce, mixed with 3½ ounces of cold, unboiled, filtered water, and then add one ounce of lime water. Give four ounces of this every three hours. At the end of twenty-four hours, if digestion is normal, 4½ to 5 ounces may be given every three hours; seven feedings in the twenty-four hours.

After three days of this feeding, the food may be strengthened by taking the upper four ounces from each of two or three quart bottles of milk sixteen or more hours old. Of this four ounces use for each feeding 1½ ounces, mixed with 3½ ounces of water, and one ounce of lime water. Give this quantity every 3½ hours; six feedings in the twenty-four hours. After two or three days of this feeding, the food may be gradually strengthened until it is of the strength for a child of six months. It should then be given every four hours; five feedings in the twenty-four hours.

Feeding a Child Nine Months of Age with Diarrhea.—The management is the same, except that the quantity, not the strength, is increased more rapidly, owing to the greater bulk required in a nine-months-old child.

Minimized proteid must not be relinquished: This abides as the supreme disideratum.

Feeding a Child in Second Year with Diarrhea.—Feeding which has thus far fulfilled each and every and all physiological and pathological indications, would now be fundamentally defective. The older child must have higher proteid.

The crippled organs cannot utilize higher milk proteid. Nothing is more intolerable to them. Vegetable proteid is now logical, valid, prerequisite, imperative.

Physiology dictates the addition of cereal to the food of a normal child at the sixth or seventh month, but the secretions for its digestion are not sufficiently developed to justify its use as the exclusive food in diarrhea, until about the twelfth month.

The anomalous mortality from diarrhea in young infants is artificial, and has as its principal cause the abnormal and singular use of cereals. In older children there is a spurious mortality superinduced by the misemployment of animal broths. Stress of diarrhea and growth make demand for constructive material paramount. Animal broth is destitute of constructive element; rich in extractives which stimulate metabolism while it should be conserved—the child wastes rapidly. Death ensues from a general starvation of every part. The young infant dies from inanition with angioneurotic edema on vegetable proteid, because he cannot utilize it. To parallel this, the older child is given as aliment that which is characterized by destitution of constructive element.

The pronounced tendency to renal determination is intensified by the rich content of muscle and bone extractiveness in broth. Physiological and pathological studies furnish final negatives; bedside reflections make them abhorrent.

Beef juice must be eschewed and interdicted. It causes the stools to become putrid, foul-smelling; looseness is aggravated; the delicate nervous organization overstimulated—every phase of the disorder is accentuated.

Vegetable proteid is the only tissue-forming material which the disqualified organs can utilize.

Cereal checks looseness, repairs waste, vitalizes languishing functions. Cereal is indispensable to the successful treatment of diarrhea in the second year. It must be the sole food in diar-

rhea from the end of the first year, with its use recovery is rapid, complete, perfect, permanent.

If a child is bottle-fed, the cereal should be given in the form of a gruel and from a bottle. If spoon-fed, the cereal should be given hot, and with a little butter and salt; never with cream or milk, and never with broth or beef juice added. It must not be given with sugar.

For a child of one year, give four ounces of gruel every four hours, five feedings in the twenty-four hours. If this quantity does not satisfy, water may be allowed midway between feedings. As this older child has better muscular development, water between feedings does not cause the same amount of exhaustion of the vital forces and of the nervous centers. There is, however, a limit, and great care must be taken that the child is not allowed quantities of water at frequent intervals.

The cereals of greatest value and most to be depended upon in diarrhea in the second year are barley (whole or pearl barley), Imperial Granum, arrowroot, rice, cream of wheat. They must all be cooked with water, never with milk.

Imperial Granum and arrowroot should be cooked thoroughly for one-half hour; pearl barley, three hours; rice, one hour and cream of wheat, one hour. They should all be salted as for the table, while cooking.

Barley, rice and cream of wheat should be strained. Imperial Granum and arrowroot need not be. The last two should be cooked fresh for every feeding; the others cooked fresh every twenty-four hours and kept in the refrigerator until needed. They should be served hot.

Mothers, nurses, and even physicians often say a child refuses cereal. Wait! Hunger soon compels them to accept it. A child never starves because the dictum of the palate is not subserved. Only that food which is sustaining and curative is ever permitted. When tissue-hunger makes demand, it is taken readily; until that time it is not needed.

The channel purified of sewage and made sanitary, the management and feeding prescribed and proscribed proves consummate, without fault or blemish, with no dark side—every case of acute diarrhea is well within one week.

Feeding of Neglected and Mismanaged Cases from Three to Nine or Ten Months of Age which Have Become Subacute or Chronic.—Cases that have been ill for weeks, possibly for months, until there is a chronic disease of the intestines, are the troublesome, stubborn, unmanageable ones, and are the cases that swell the death-rate. In this extremity, a happy consummation expiates the promulgation of a heresy—an unorthodox food. I have proved condensed milk in this class of diarrhea, with the result that conviction, and conscience compel recognition and advocacy.

In these neglected cases one of two things will save life—breast milk or condensed milk. A bottle-fed child of six or eight months can seldom be induced to take the breast.

With profound apprehension of the evil effects from the prolonged use of condensed milk; and despite prescience of consequent vehement criticism, I prescribe condensed milk in subacute and chronic diarrhea in young infants, inasmuch as it is the only food, except breast milk, that will save life.

For temporary uses in such cases it does incalculable good; its prolonged use does incalculable harm. Condensed milk may be made beneficial or baneful, conformable to its use or abuse. Judiciously used it will save life where nothing else can. Injudiciously used it is a prolific source of disease. I would not advocate its use had I not an experience of years during which it has not once failed me.

The clinical fact that infants who have been continuously fed on condensed milk for any prolonged period have an abiding predisposition to diarrhea of fatal type, does not deter me from having recourse to it in the restricted manner indicated, and in the cases alluded to, which I am confident are to become less frequent in the near future, owing to improved management, and rational, logical, physiological feeding.

How to Use Condensed Milk.—For a baby three months of age with subacute or chronic diarrhea, take one teaspoon level full of canned, sweetened condensed milk (scrape off the undersurface of the spoon), put it into a china vessel, add to this with a teaspoon, twenty-four teaspoonfuls of water which is actually boiling. One ounce of this should be used for each feeding. (The rest to be thrown away. Prepare fresh for every feeding).

After cooling to temperature for feeding, add two teaspoonfuls of lime water to one ounce of the mixture, and give this quantity (one ounce and two teaspoonfuls), every four hours.

This should alternate with one ounce of hot water and two teaspoonfuls of lime water, every four hours. (Water and food alternating every two hours.)

At the end of twenty-four hours of this management, the movements become less frequent and improve in character. After forty-eight hours, if improvement has progressed, the quantity may be increased to two ounces every four hours, with one-half ounce of lime water added. Alternate this with two ounces of hot water and one-half ounce of lime water.

After forty-eight hours of this management, if the movements have become normal, two ounces of the condensed milk mixture with one-half ounce of lime water, is given every two hours, and the water discontinued.

One week later, everything being normal, the food is strengthened by making it one teaspoonful to sixteen, or two, to thirty-two of boiling water. Give three ounces of this mixture, with one-half ounce of lime water, every three hours. This strength is not exceeded—one to sixteen—at any period during the condensed milk feeding.

The effect of this feeding is so miraculous in infants apparently hopelessly ill, that it is difficult to induce mothers or nurses to discontinue it when the patient has recovered. It is quite impossible to bring any mother who has experienced the effect on a prolonged, seemingly hopeless, case of diarrhea to a discontinuance of the use of condensed milk. The responsibility of the physician is great. The condensed milk must be stopped or that which saved the child's life will later lead to scurvy-rickets and to irremediable deformity.

Discontinuing Condensed Milk.—With the advent of propitious autumn weather, if digestion, movements, and appetite are good, condensed milk should be supplemented gradually, surreptitiously.

Instructions.—Take the top ounce from a quart bottle of milk, which has been standing upright on ice for sixteen hours from the time of milking, or in town six hours after it is received in the nursery. Keep this one ounce of cream on ice until needed. One teaspoonful of this cream is added to every *second* bottle of the condensed milk food, just before feeding.

After three days of this feeding, if the stools are normal, and the appetite good, one teaspoonful of cream is added to *every* bottle. One week later, or ten days from beginning the addition of cream to the bottle, if the appetite and movements are good, *two* teaspoonfuls of cream (top ounce from two quart bottles), are added to *every* bottle.

After continuing this feeding two weeks, the condensed milk is gradually lessened, the top cream gradually increased. It now becomes important to take more from the top of each quart bottle of milk in order that there may be a slowly increasing percentage of proteid in the food.

Feeding in Subacute and Chronic Diarrhea in the Second Year.—With cereal as the only food every case comes under control in a surprisingly short period.

In a bottle-fed child barley (whole barley) gruel, four to six ounces every four hours—five feedings in the twenty-four hours. If spoon-fed, cereals served hot, and with butter and salt every four hours—five feedings in the twenty-four hours. All other food is interdicted. Cold, unboiled water is allowed freely.

Irrigation.—This is an abused, overwrought treatment. Abdominal distention and mortal collapse consequent upon high, large, frequently repeated irrigations are unfortunately often encountered.

To supplement the action of castor oil it is sometimes expedient to irrigate on the first day. Repeated irrigations are exhausting and seldom advisable. These precepts are founded on the rock of experience. Administered faithfully, they will bring the frailest, disease-tossed, bark safely, securely to the harbor of health.

TWO CASES OF EPILEPSY, THE RESULT OF GASTRO-INTESTINAL DISTURBANCE.*

BY FRANK H. MURDOCH, M.D.,
OF PITTSBURG, PA.

Regarding the pathogenesis of epilepsy a well-known author has recently expressed himself as follows: "For some years the writer has been impressed with the facts forced upon him, not only as the result of the study of his own cases, but by the accumulated researches of Raymond Petit, Voisin, Smith and Herter, Mott and Halliburton, and later by Carlo Besta, and other Italian investigators, that toxemia enters more largely than is generally supposed into the pathogeny of epilepsy, and this is apparent, as Voisin has pointed out, in the general resemblance and mode of occurrence between the epileptic attacks, and certain ordinary forms of poisoning in which the nervous system is affected. In such cases the element of convulsion, and the mental disturbance have features in common, and it would appear that the occurrence of the fit betokens the accumulation in the body of some particular toxic agent, the unwelcome presence of which gives rise to a convulsion when the point of cell-tolerance has been reached. He also states that autotoxemia may occur in three different ways. First, in the existence of a toxemia of gastro-intestinal origin, which was described originally by Bouchard, and later by Herter and Smith, as well as by the author just quoted. Second, by the introduction of certain familiar cocci into the circulation, and third, the presence in the blood of a specific poison called cholin." [1]

The cases which I wish to report were due to autotoxemia, one resulting from disturbance in the stomach, and taking the form of *petit mal*, the other being associated with intestinal disturbance, and taking the form of *grand mal*.

Case I.—Miss M. S., aged eighteen years, consulted me on June 21, 1904, and gave the following history: A year and a half ago she began to be troubled with vomiting during or immediately after meals, occasionally through the day, she suffered from attacks of nausea, and often at such times vomited a very sour fluid. Six months ago she lost consciousness for a few moments while at church, and similar attacks have been coming on with increased frequency ever since, so that for the last two or three months she has had an average of two or three attacks a day, and during the last two days she has had eight or nine attacks each day. There is a distinct aura which begins in both heels and passes up the posterior aspect of the legs, then along the spine, and when it reaches the lower dorsal region she experiences intense nausea, and endeavors to induce vomiting by passing her fingers as far back over the root of the tongue as possible. Simultaneously with the nausea she loses consciousness, for after the attack she has no

* Read at a meeting of the Gastro-Enterological Association, in New York, April 24, 1905.

recollection of having made an attempt to induce vomiting. She looks pale, and has lost twelve pounds in weight. Her menses are scanty and irregular. Appetite poor, bowels regular, bad taste in the morning. Inflation of the stomach shows that its lower border reaches the navel, and the right kidney is movable in the second degree. The gastric secretions are normal. The urine is acid, and contains neither sugar nor albumin. Her stomach in the morning before she has eaten anything, contains a large quantity of mucus mixed with bile. The treatment consisted in proper diet, iron and arsenic, and gastric lavage. It is a remarkable fact that after the first washing out of her stomach the epileptic attacks ceased, and I am glad to say, did not return. She spent the summer in the mountains, being careful as to her diet, taking the iron and arsenic, and washing out her stomach two or three times a week. I saw her on October 11, 1904, and she had gained ten pounds in weight, her menses were regular as to time, and sufficient in quantity, and in fact she was enjoying excellent health.

Case II.—On October 7, 1901, Mr. A. D., aged thirty-two years, merchant tailor, consulted me and gave the following history: Two years ago he began to suffer from frontal headaches, after the headache had lasted for three or four hours he began to vomit a greenish bitter fluid mixed with food particles. The vomiting continued for twenty-four or forty-eight hours, during which time he had to keep his bed. After the attack he felt quite well for three of four months, then, without any apparent cause, the headache and vomiting would return. Lately the attacks have been coming on every month. On the night of September 1, 1901, he vomited after having retired, but lay down and went to sleep again. Soon after, he woke a young man who happened to be sleeping with him that night, by having a violent convulsion. His friend went for a physician who was of the opinion that the attack was epileptic, as the patient was unconscious, had foam on his lips, and had bitten his tongue. On October 1, during the day, he had headache and vomiting, but no epileptic attack. His appetite is poor, bowels constipated. Examination shows that the apex beat is displaced, being 2½ inches below, and 1 inch within the nipple line; liver normal, stomach and intestines contain much gas. When the stomach is inflated with air the lower border reaches a point 1½ inches below the navel, and the ascending colon is considerably dilated. The gastric secretions are normal, free hydrochloric acid being + 32, total acidity, 68. The urine is acid, specific gravity, 1.020, and contains neither sugar nor albumin, but indican in excess. Treatment consisted in a regulated diet, and flushing the colon every day with normal salt solution. After beginning treatment the patient had no more headache or vomiting, and no further epileptic attacks. Now, it is impossible to tell whether this patient had more than one convulsion or not, for, as is well known, when attacks come on at night a person may be epileptic for years without knowing it.

In regard to diet in epilepsy, Hamilton[2] says, "I have no reason to change my opinion, advanced nearly thirty years ago, and which has been shared by others, that an excessive nitrogenous diet is apt to aggravate the disease. Merson, adopting the idea of Hughlings Jackson, that it is the nitrogen that leads to explosiveness and instability, conducted a series of experiments at the West Riding Asylum, which showed that a meat diet, not only produced a dull languid condition with an increased temperature, but that the attacks were more frequent." Burney Yeo[3] is of the opinion that epileptics should not have meat more than once a day, and at the Craig Colony for Epileptics in New York, patients are allowed meat once a day every day in the week except Friday.[4]

It has been my experience that patients with achylia gastrica do better on a diet from which red meats have been excluded, while in hyperchlorhydria the reverse obtains. It would be interesting to know the state of the gastric secretions in those epileptics in which the disease is aggravated by a nitrogenous diet.

Of the several forms of diet recommended in epilepsy, Turner[5] has found that of salt starvation the most satisfactory. The chief feature of the method lies in the diminution of the bromide dose, from 20 to 30 grains of one of these salts at bedtime being sufficient.

THREE ADDITIONAL CASES OF PRIMARY SARCOMA OF THE STOMACH.[1]

BY HARLOW BROOKS, M.D.,

OF NEW YORK;

PATHOLOGIST TO THE MONTEFIORE HOSPITAL; VISITING PHYSICIAN TO THE CITY HOSPITAL.

YOUR president has been kind enough to permit me to report three additional cases of primary sarcoma of the stomach, not as a paper, but as a postlude to the very interesting and instructive study which Dr. Manges has just presented to us. I feel somewhat embarrassed to present these cases to you in this abbreviated and superficial way, for I believe that they and the subject warrant an extended study, but in the few days in which I have had notice of your indulgence I have had time to extract in a very brief way only, the most essential notes on the cases which I hope to discuss more fully at some future time when I shall be better prepared on the subject which Dr. Manges has so opportunely brought to our attention.

1 Read before the Gastro-Enterological Society, April, 24, 1905.

Case I.—J. M., female, aged fifty-seven years. The patient entered the hospital in a delirious condition, at times she cleared up somewhat, but was not mentally competent at any time. Friends stated that she had been alcoholic since the age of fifty. Previously she had always been in good health until within the past two months, when she commenced to lose strength and appetite. Her only complaint has been of general weakness. Temperature on admission, 99° F., pulse 86, respiration 24.

The physical examination was practically negative, except for the following conditions—pulse, weak, regular, considerable degree of arterial disease and tension.

I saw the woman several times but was never able to make anything definite out of the case, other than general arteriosclerosis and senility. The extreme emaciation and a peculiar brownish pigmentation of the skin, at one time gave rise to a question of Addison's disease and Dr. Lambert, under whose care she was, insisted throughout that the condition was one of new growth cachexia, though careful examination, particularly of the flaccid abdomen gave no hint as to its location.

Milk only was supplied for nourishment, this was retained and apparently fully digested. No gastric tenderness or tumor was present. Whisky and strychnine were administered from time to time, but the weakness and emaciation steadily increased. After she had been in the hospital fourteen days, she vomited one night, four to six ounces of blood-stained material. This was not saved by the nurse. In the morning a small amount of coffee-ground vomitus was also discharged. The patient at this time was seen to be moribund and she died within a few hours.

Abstract of Protocol.—General appearance—Emaciated and senile. *Heart*—Brown atrophy; aneurismic dilatation of the sinuses of ascending arch. Marked coronary sclerosis; moderate arteriosclerosis of arch of aorta. *Thyroid*—Left lobe contains an encapsulated mass, thought to be an adenoma. *Lungs*—Chronic miliary tuberculosis of apices. *Lymph nodes*—Large, anthracotic and tuberculous. *Liver*—Fatty degeneration and chronic congestion. *Spleen*—Old-healed infarctions. *Pancreas*—Negative. *Stomach*—There is an hour-glass constriction 5 cm. from pyloric ring. Both the upper and lower curvatures of the stomach show thickening of the walls without definitely circumscribed tumor formation. In places the mucous membrane lies free over the surface of the new growth, but in other places the mucous membrane is sloughing and is replaced by a layer of mingled blood clot and necrotic tumor material. The stomach as a whole is small, and except for the ulcerated areas its mucosa is free and anemic. *Intestine*—The intestine is adherent, in a few places, to the peritoneum and in these areas minute tubercles are found, supposed to be recent tubercles, corresponding to these points internally, minute ulcerations of the intestinal mucosa are seen in a few places. These ulcers are thought to be tuberculous. *Adrenals*—Negative. *Kidneys*—Chronic interstitial nephritis. *Genital organs*—Atrophic. *Blood vessels*—The inferior vena cava presents a dilatation filled by recent thrombus located just above the bifurcation. The descending aorta and the large trunks of the abdomen and pelvis show marked arteriosclerosis.

The gross anatomical diagnosis was senility, complicated by gastric carcinoma and adenoma of the thyroid gland with healed pulmonary tuberculosis terminating with thrombosis of the inferior vena cava.

Greatly to my surprise microscopical examination showed that the gastric growth was a small round-cell sarcoma, apparently originating in the stomach wall. The minute nodules found in the peritoneum were also found to be sarcomatous.

Case II.—The case was that of a male, fifty-seven years of age, a baker by occupation. He first came to me complaining of pain just above the umbilicus. His previous and family history were good and gave no hint as to the nature of the present trouble. At times paroxysmal vomiting occurred, usually when the stomach had been overloaded. The vomitus never contained blood.

The man was a large and powerful German, very well nourished. Examination of chest and abdomen gave only negative results, perhaps due to the large amount of abdominal adipose. Hemoglobin, 65 per cent. No hyper-temperature, pulse and respiration normal. He was given a simple rhubarb and soda mixture and was advised as to diet.

Two months later he returned showing marked emaciation, so that palpation of the abdomen was now an easy matter. He still complained of abdominal pain, sometimes very severe and cramp-like in character. He had become very weak, extremely pale and had lost flesh in a truly astonishing manner. He had no desire for food and even fluids were followed by extreme distress.

Palpation of the abdomen disclosed a firm globular mass in the hypochondrium a little to the right of the median line. Inflation of the stomach and ausculatory percussion demonstrated the mass to be apparently attached to the stomach, which was not, however enlarged. Considerable tenderness was present over the mass. Examination of the gastric contents, after a test meal, showed delayed digestion, and apparently more or less pyloric stenosis. Both free hydrochloric acid and lactic acid were found in small amounts. No blood was found and the Boaz-Oppler bacillus was not present. The patient was given a solution of dilute hydrochloric acid and was placed exclusively on a milk-diet. He was seen frequently. Considerable gain of weight and improvement of symptoms was made under this treatment but no decrease in the size of the tumor was observed and he was strongly

advised to submit to an exploratory laparotomy. This was performed at the Hood Wright Hospital by Dr. Lucius Hotchkiss.

The pyloric extremity of the stomach was found to be involved for a distance of about 10 cm., by an infiltrating growth, subperitoneal, but of such extent, that considering the condition of the patient, it was not thought prudent to attempt enucleation or other operative procedure.

The patient died about ten days after the operation and, as we were unable to obtain an autopsy, the house surgeon, Dr. Hanscome, made a thorough exploration of the abdomen through the operation wound and removed portions of the various viscera for examination.

The growth was found to be both submucus and subserous, infiltrating between the walls of the stomach. Microscopical examination demonstrated it to be an angiosarcoma. No metastases were found in any part of the body, though, as I have stated, a complete autopsy was not performed.

Case III.—R. L., female, about fifty years old. Entered Gouverneur Hospital, July 4, 1904, in the service of Drs. Huddleston and Braunlich. Two years ago she had attacks of flatulence, diagnosed as "catarrh of the stomach." There was pain after eating, sour taste in the mouth and similar symptoms. Eight months ago she began to lose flesh and strength. She had occasional attacks of pain over the epigastrium and vomited once in a while, but she had never ejected material resembling blood. On two occasions she was at Mt. Sinai Hospital where a diagnosis of gastric carcinoma is said to have been made. During this time she twice vomited blood.

The emaciation and asthenia have constantly increased, so that the patient is now bedridden and has developed bed sores. She is extremely anemic, has fever at times and is much troubled with constipation.

Inflation of the stomach demonstrated the lower border to be two fingers breadth above the umbilicus. Although abdominal walls were very thin, owing to the great emaciation; no gastric tumor could be demonstrated and gastric tenderness was doubtful.

The general appearance was that of a woman of medium height, extremely emaciated and of poor muscular development. The skin was very pale and of a waxy appearance. She had an expression of anxiety and suffering and was very apprehensive of being given pain.

Examination of thorax was negative except for marked emaciation. There was slight edema of the left leg, but otherwise the extremities were negative. Examination of the abdomen on many occasions always gave absolutely negative results. Vaginal and rectal examinations were also negative.

Frequent examination of the stomach contents showed the constant presence of free HCl and also of lactic acid. The Boaz-Oppler bacillus was present.

The anemia was profound and the hemoglobin finally sank below 10 per cent., as determined with Dare's instrument; the red-cell count below 1,000,000, and the blood presented the characteristic picture of a very grave secondary anemia. The urine constantly showed the presence of slight traces of albumin and occasionally considerable numbers of casts were found. The weakness, emaciation and anemia constantly progressed in spite of rectal and gastric alimentation and she died, July 16.

A post mortem was absolutely refused and consequently the only possible examination was made per vaginam, but this was done in a quite satisfactory manner, all the thoracic and abdominal viscera being removed and submitted to examination.

The following extracts of the examination touch only on the points of direct interest: "The entire pyloric end of the stomach shows a thickening of the walls, chiefly in the muscular and submucous layers. This thickening is diffuse, not nodular, and is very firm in consistence. The mucosa of the stomach is very anemic and in a few areas minute hemorrhagic extravasations are to be made out. The mucosa moves freely over the submucosa and is apparently not at all involved by the process noted. Although the entire pyloric ring is thickened, it does not amount to a clinical obstruction."

Both gross and microscopical examinations of the other viscera showed only the changes consequent upon severe anemia. The lymph nodes were in particular inspected, but no metastases were found except in certain of the smaller nodes of the gastric mesentery, which showed a few small patches of invasion.

Microscopical study of the growth showed it to be a fibrosarcoma, though in places the diagnosis of myxosarcoma might be granted.

To my mind there is no doubt but that primary sarcoma of the stomach is much more frequent than is generally thought to be the case. Unquestionably this is due to the fact that microscopical examination of tissues removed post mortem is not invariably resorted to. The four recorded by me have been discovered in a series of some 1,200 consecutive autopsies, and in each of these instances the gross specimen aroused my suspicion as to the unusual nature of the growth. It stands to reason that gastric sarcoma may, in many instances, resemble the more common gastric carcinoma, and it is my firm belief, that were every case of stomach neoplasm examined microscopically, we would find sarcomata much more frequent than my statistics indicate.

Judging from my four cases, a very small and insufficient number, it is true, it seems that in several respects, sarcoma of the stomach differs materially from the usual course of gastric cancer.

There is less tendency to involvement of the gastric mucosa and more toward infiltration of

the muscular walls. Metastases seem to be less frequently formed and of later appearance and the course of the disease is longer than usual in carcinoma.

It has seemed to me for some time, after a study of my own cases and of such as I have found in the somewhat meager literature of the subject, that it may be possible to make a differential diagnosis in some cases of gastric growth, between cancer and sarcoma of the stomach. Obviously this can be done in but a small number of cases, but in these it is apparently of considerable importance since the sarcomata seem to present a more hopeful field for surgical intervention than the carcinomata on account of the less tendency to general metastasis and invasion by contact.

I feel certain that in the instances cited above the distinction should have been made in Cases II and III particularly, as it was possible to satisfactorily palpate the general abdomen contents in these cases.

The presence of gastric tumor, with both free hydrochloric and lactic acid in the stomach washings, the long course of the disease without discoverable metastasis, with little or no blood in vomitus, even in the later stages of the disease, should, in my opinion, lead at least to the serious consideration of the possibility of gastric sarcoma.

In closing these case reports permit me to say that in my opinion cases of gastric tumor should be submitted to surgical council, even to exploratory laparotomy, just as soon as diagnosis becomes a matter of tolerable certainty.

MEDICAL PROGRESS.

MEDICINE.

Tuberculous Meningitis.—W. F. Cheney (*Journal A. M. A.*, May 20) reports and comments on three cases of tuberculous meningitis with special reference to the diagnosis. He mentions the indefiniteness of the early symptoms, and says that we should always be suspicious of tuberculous meningitis in a child in illness with associated digestive disturbances, slight fever and irritability of temper. Stupor is more significant, but it may also be due to intestinal toxemia or some acute infection, but in such case there is usually a higher fever. Evidences of intracranial pressure, such as pupillary abnormalities, local paralyses, irregularities, etc., are still more definite indications, but these, like the mental condition, may vary from day to day, thus giving rise to false hopes of recovery. Rigidity of the neck muscles is a very valuable sign, only likely to be simulated by disease of the cervical vertebræ or rheumatic torticollis, and in these other symptoms of meningitis are apt to be wanting. The Kernig sign, so valuable in the adult, is, according to Cheney's experience, difficult to elicit in children, owing to their fear of manipulation. The white blood count is of value, a moderate leucocytosis pointing to tuberculous rather than to other forms. Lumbar puncture furnishes negative evidence of value, with the other symptoms present, a clear fluid, free from microorganisms is characteristic of tuberculous meningitis. One of his reported cases is of interest on account of its occurrence in an adult, its clinical resemblance to cerebrospinal meningitis, and from its being the only one of the three in which an autopsy was obtained. We are apt to associate tuberculous meningits with infancy, but it can be excluded at no period of life. In this case the low leucocytosis and the lumbar puncture findings confirmed the diagnosis of tuberculous meningitis during life, and the autopsy revealed a pre-existing lung focus. Tuberculous meningitis is always secondary to the disease somewhere else in the organism. The article concludes with remarks on the differential diagnosis from other conditions, and especially from the other forms of meningitis.

Headache From Malaria.—C. J. Stedman (*Journal A. M. A.*, May 27) reports a peculiar case of malaria, without temperature symptoms, occuring in the middle of an Arctic winter. The only symptom—headache—appeared each forenoon and lasted five or six hours. The patient acknowledged no previous malarial infection. The blood examination showed no perfect organisms, but numerous malarial spores, and these rapidly disappeared, with the symptoms, under quinin. He regrets that the blood examination was not made earlier and the exact character of the parasite determined, though the appearances indicated the tertian organism. The case is reported on account of the unusual circumstances and manifestations, and as a suggestion of the importance of early blood examination.

Economics of Medical Organization.—J. Madison Taylor (*Journal A. M. A.*, May 27) deprecates the lack of professional and scientific cooperation in the medical profession. There should be more frank and full discussions and interchange of opinion; more professional consultations between general practitioners, and more interest and activity in local medical organizations. "If we show that we have confidence in each other the general public will have more confidence in us." He suggests the clubbing together of physicians of moderate means in the purchase of professional works and subscription to medical periodicals, thus multiplying their resources for professional information at slight individual cost, and the more freely availing themselves of each other's professional knowledge and skill in the common exigencies of general practice. Lastly, he speaks of the need of more influence of the profession in public matters and in legislation, which can only be remedied by better organization and more active work on our part. "If," he says, "each reputable physician in America were a member of the American Medical Association, and fulfilled his duty in local and centralized organizations, not only would the power of medical opinion become invincible, but individual self-respect would reach a high plane. Not only so, but individual values being thus raised, proportionate earnings would follow. The public is perfectly willing to pay well for value received, and would quickly become content to pay more for better service, not only in times of exigency for personal attention, but for the knowledge that through and by intelligent watchfulness of local and national interests they would be better served, better protected, and that future needs would be anticipated and met."

Action of Roentgen Rays on Leucemia.—The beneficial action of the Roentgen rays on leucemia, reported from so many clinics, could also be observed by F. Lommel (*Münch. med. Woch.*, May 9, 1905).

In one case the leucocytes dropped from half a million to normal in three months, and the myelocytes disappeared altogether. The spleen was no longer palpable at the end of treatment, and the patient lost his anemia and could do light wrk without fatigue. It seems, however, as if the cure is not permanent, for when the patient was seen again after several months, his blood contained over 50,000 leucocytes. The first sign of recurrence is the appearance of myelocytes in the blood. Good results were also seen in Hodgkin's disease, but the patient died of some other affection, so that it was impossible to say if the cure was permanent.

Appendicitis Work;—Different Views.—R. T. MORRIS (*Med. Rec.*, May 27, 1905) says that although formerly he used to forbid morphine altogether his views on the subject have changed and he now gives it cautiously in cases in which there is great restlessness. The drug is still regarded as a double-edged sword, however. Both gauze packing and iodoform gauze have been abandoned altogether, as well as the use of buried sutures of silkworm gut. A standard length of one and one-half inches for the incision has been adopted for nearly all instances, including cases of abcess and peritonitis, and it has been found safer to deal with adhesions by touch than by sight. The time limit has also been greatly reduced, and now it is common to have the time from the first incision to the last suture occupy not more than seven to eight minutes. All patients are operated, even if moribund, a preliminary infusion of salt solution being given: adhesions are freely separated if necessary but not otherwise, and the idea of flushing out the abdomen has been dropped. After eliminating the features which seemed to have a special death-rate of their own, viz., gauze packing, iodoform gauze, long incisions, and the expenditure of time in unnecessary detail of work, one hundred consecutive operations were published with a two per cent. death-rate. The author does not favor the removal of the normal appendix in the course of other operative work, and he now uses a cigarette drain in all cases in which pus or septic débris have been left in the peritoneal cavity. The dictum of operating as soon as the diagnosis is made holds good, with certain exceptions, but it is still a question what to do with patients who are convalescing from the attack. In interval cases it now seems best to operate only when on palpation the appendix is found to be the definite seat of chronic infection or of adhesions which cause symptoms.

Ailurophobia and the Power to Be Conscious of the Cat as Near, When Unseen and Unheard.—S. WEIR MITCHELL (*Am. Med.*, May 27, 1905) says sufferers from cats may be classified as follows. (1) Asthmatics—cat asthma. (2) Cat fear, with or without sequent excessive, emotional manifestations, and only on sight. (3) Cat fear. Power to be sure an unseen cat is near. Symptoms same as in Class 2, and apt to be extreme. (4) Those of the last class can detect the cat by smell, or may sometimes and not always. (5) Cases occur in which the consciousness of a cat as present through its smell once existed, but does not now, and yet the ability to detect unseen cats remains. (6) It is therefore likely that the cat emanations may affect the nervous system through the nasal membrane, although unrecognized as odors. Many of the victims declare even strange cats seem to have an unusual desire to be near them, jump on their laps and follow them.

Review of the Tuberculosis Problem.—In a review of this subject DE L. ROCHESTER (*Buffalo Med. Jour.*, June, 1905) considers that the following precautions should be adopted by those suffering with tuberculosis of the lungs: (1) The consumptive should kiss no one; and no one should kiss the consumptive on the mouth; (2) the consumptive should never lend his handkerchief to anyone or borrow a handkerchief from anyone; (3) the eating and drinking utensils of a consumptive should be thoroughly boiled after he has used them; (4) during the act of coughing he should hold a piece of cheesecloth before his mouth, which may be burned or boiled afterward; (5) gauze or cheesecloth should be used to collect the sputa, and afterward burned or boiled, and (6) the sheets, pillow cases, night-clothes and underclothing of consumptives should be boiled for half an hour before washed. The author advocates the establishment in every community of two sanatoria, one for advanced and one for incipient, cases of pulmonary tuberculosis. By the enactment of an ordinance, every person with pulmonary tuberculosis who cannot receive proper care and be accommodated with any room at home to be occupied by himself alone, should be compelled to go to one or the other sanitariums. Two sanitariums are advocated: (1) because the treatment of the two classes of patients is decidedly different; (2) because the constant presence of advanced patients and the occasional painful death of one or more have a decidedly depressing influence upon those having incipient disease. If every case of pulmonary tuberculosis were reported to the health department, the department could send an inspector and determine whether such case is one for home or sanitarium treatment. Instruction in regard to destruction of sputum and feces, in regard to precaution as to personal contact with others and in regard to disinfection of apartments lately occupied by the tuberculous, are all of value in checking the spread of the disease; but it is the opinion of the author that if a plan of compulsory reporting of cases and compulsory removal of suitable cases to their proper sanatoria will be much more efficious than all the other procedures in ridding us of the Great White Plague.

Origin of Aromatic Bodies in the Urine.—The general opinion to-day is that most of the aromatic bodies commonly encountered in the urine (indican, skatol and phenol) are a result of bacterial decomposition in the intestines, and many authors go so far as to say that without the latter there can be no indicanuria. It is therefore interesting to note that K. LEWIN (*Wien. klin. therap. Woch.*, May 21, 1905) has succeeded in obtaining phenol by the autodigestion of tissues in vitro, where bacterial activity could be absolutely excluded. If rabbits are poisoned with large doses of phloridzin, so that an active breaking down of proteid tissue is brought about, enormous amounts of phenol and indican will appear in the urine. The urine of patients suffering from carcinoma will often show an excess of indican, but only if cachexia has been present. The indican here is very obviously derived from the decomposed proteid tissue and not from bacterial activity.

SURGERY.

Acute Pancreatitis.—A contribution to this important subject is furnished by NOBE (*Archiv f. klin. Chir.*, Vol. 75, No. 3), who reports two cases cured by operation. In one the diagnosis of a perforating gastric ulcer had been made, in the other nothing definite could be made out. In the first case there was no fat necrosis, but on going through the lesser omentum, a dark red, swollen mass could be made out, dating apparently from the pancreas. There was a good deal of fluid present. In the other case

a sloughing mass was found at the site of the pancreas, which was removed. Both of the cases were tamponed and made a very favorable recovery. From a study of published cases, the author believes that the approach through the lesser omentum is the most satisfactory.

Comparative Surgery.—HARVEY CUSHING (*Bull. Johns Hopk. Hosp.*, May, 1905) outlines the plan which has been in use at the Johns Hopkins Medical School, of the development of the plan of teaching operative surgery, which is a distinct departure from the time-worn, yet excellent methods of conducting an operative course, which for the past generation has been widely adopted and generally regarded as most practicable by the surgical teachers in the leading medical institutions. This plan consists in endeavoring to emphasize and drill into the students the following points: (1) Surgical cleanliness, which must be learned early and become a successful operator's second nature, and which is necessarily disregarded in the methods used in teaching operative surgery in the dissection room; (2) the ability to dissect living tissues without so damaging them as to prevent perfect reactionless healing; (3) an acquirement of skill in the proper control of hemorrhage, and (4) particular technic of visceral surgery, whether abdominal, thoracic or intracranial. To properly emphasize these points the course has been started upon living animals, on which all the formalities that would be observed in regard to a patient admitted for treatment to the surgical wards of the hospital have been followed. Clinical histories have been kept on regular hospital history sheets; the effect of anesthesia on the pulse and respiration has been carefully recorded; the detail of the operative preparation both for the staff and patient has been followed; pathological and postoperative notes have been made, and in case of a fatality a formal autopsy performed, and its results added to the record. The author considers that after a training of this sort, and with an acquirement of proper surgical reflexes, a student, when his turn comes, should be found a safe and valuable helper in the hospital operating room, where blunders in technic must not occur; and, furthermore, he may with profit to himself be an understanding onlooker at the surgical work of others.

A Case of Repeated Acute Intestinal Obstruction Following Ovariotomy.—E. D. TELFORD (*Med. Chronicle*, May, 1905) in reporting a case, calls attention to the fact that the occurrence of acute intestinal obstruction after the older operations of ovariotomy and hysterectomy appears to have been not uncommon. The modern use of peritoneal flaps in covering in raw surfaces and stumps has very materially diminished this risk, yet there always remain cases in which the possibility of subsequent intestinal obstruction constitutes a very real danger. This danger is especially marked in those cases in which extensive intestinal adhesions are separated in the removal of ovarian tumors or in the extirpation of matted tubes and ovaries. In such cases areas of bowel may be left in a raw, denuded condition, and such surfaces readily form adhesion liable to set up serious obstructive mischief at a later date.

Anatomical Points in Prostatectomy.—It was J. W. S. Gouley, of New York, who, together with Bottini, of Italy, between 1865 and 1886 kept alive the operation of prostatectomy. It had been devised by the French surgeon, Mercier, and for the first ten years or so after his retirement from active work, it was Gouley who actually stood alone in the practice of prostatectomy. FRANCIS S. WATSON (*Annals of Surgery*, April, 1905) describes Gouley's operation as that of rapid fingering creation to the size of the prostatic urethra by the forefinger. The author states it to be identical with the operation employed by Goodfellow, of San Francisco, who not knowing Gouley's description, assumes it to be original with himself. One of the most important anatomical points in connection with rendering possible the digital enucleation of the prostate, is that the three so-called lobes are definitely separable from the fibrous sheath enclosing them. The thickness of this is in some cases most conspicuous. There is a well-marked interval or space between the surface of the gland and the inner aspect of the outer sheet. It is in this space that all enucleation of the gland should be conducted. The level of the lower border of the urethral aspect of each lateral lobe is a little above that of the floor of the prostatic urethra, also above the level of the ejaculatory ducts. The operation, therefore, which does not involve injury of the floor of the prostatic urethra, will not injure the ducts. Thus enucleation without injury to the ducts is theoretically at least possible. This is a contravention of Dr. Young's holdings, who claims that the digital enucleation of the gland is a proceeding which takes place in the dark and which must be injurious to the ducts. The author emphasizes the fact that it is not so much a matter of technic, but rather is it important that those who are experts in this special province, should teach the profession at large that the operative treatment of prostatic hypertrophy has been sufficiently perfected to make it desirable that patients should be given the benefit of it rather than be submitted to the dangers of catheterism until surgical intervention is practically hopeless. The credit of devising suprapubic prostatestomy belongs to Belfield and McGill as certainly as it does not belong to Freyer. To him, however, is definitely due the awakening of great interest in the subject of prostatectomy in England, where, as is well known, the perineal route has never been seriously considered by surgeons. The article illustrated by photographs of the author's recent specimens, some of which show very clearly that the ejaculatory ducts may be saved even when the gland is removed by finger enucleation through the median perineal incision. In conclusion Watson states that the mortality of the perineal operation is much less than that of the suprapubic, that at least two out of three times the gland is to be found removable via the perineum and that in the other third the surgeon may proceed to do the suprapubic operation. After seven years of attention to the subject of prostatectomy, Watson concludes that he would suggest that the most valuable contribution at present possible on this subject would be to have reported cases treated by the catheter throughout with special reference to mortality and the time which elapsed between the commencement of catheter treatment and death.

Morphine-Scopolamine Narcosis.—The general opinion in Germany is voiced by M. KOCHMANN (*Münch. med. Woch.*, April 25, 1905), when he states that morphine and scopolamine alone as narcotic, is hardly ever safe since the dose of the former drug is too high. Small doses are, however, highly to be recommended if followed by one of the usual anesthetics (morphine hydrochlorate 0.01 to 0.02 gme., scopolamine hydrobromate 0.5 to 1.0 millgme. in fresh solution). Either chloroform or ether may be used but with ether the advantages are perhaps more marked. The excitation stage is shorter, less anesthetic is necessary, salivation is never troublesome and the danger of post-

operative pneumonia is considerably diminished. Some 1,200 cases have been reported with a mortality of one per cent., but many of the patients were already in a moribund condition when operated on. It may also be advisable to resort to the two drugs in smaller doses in Schleich's infiltration anesthesia.

Value of Functional Renal Diagnosis.—The general opinion concerning the value of the various methods employed for determining the functional activity of the kidneys has undergone considerable modification of late. Ureteral catheterization is employed quite generally in preference to the different segregators, despite the fact that Luys has recently described a new instrument which it said to be superior to anything previously offered. A perusal of the book written by Luys convinced G. KAPSAMMER (*Münch. med. Woch.*, April 25, 1905) that the disadvantages of segregators in general also apply here. It is particularly the fact that the urine is not collected directly from the ureters but is permitted to mix with the secretions of the bladder, which introduces a serious source of error. There can be no doubt at the present day that the only safe and reliable method of obtaining the urine from the two kidneys is by means of ureteral catheterization. Cryoscopy is no longer considered so infallible a method as it was years ago. Koranyi himself laid down definite rules but later investigations have shown that the freezing-point of the urine may vary within very wide limits both in health and in disease. The freezing-point itself is of little value since this may be modified considerably by the amount of water ingested. It is more important to estimate the freezing point of the urine first under ordinary conditions and then to give the patient a large amount of water to drink; with normal kidneys the urine will be more dilute, while in parenchymatous nephritis the concentration need not be altered. To determine this, it is not necessary to resort to cryoscopy, for the specific gravity will tell as much. Another fact which must not be forgotten is that the simple insertion of a catheter into a ureter may set up a reflex polyuria which will considerably alter the freezing-point even though the kidney of that side is in every way normal. The freezing-point of the blood is equally as unreliable. Two years ago, Kümmel stated that 0.58° to 0.60° pointed to bilateral disease, hence contraindicated nephrectomy, while 0.56° excluded absolutely bilateral disease. Recently, a large number of cases have been reported where both kidneys were normal or only one was affected, with a freezing-point of 0.60° to 0.69°. Similarly, there are instances where both kidneys were much diseased with normal freezing-point. In anemia and cachexia, low figures are the rule and if the kidneys should become insufficient, it is quite possible for the blood to freeze at the normal point. It is therefore safe to say that cryoscopy can be altogether dispensed with. Two dyes have been employed subcutaneously and their excretion studied by means of cystoscopy. Of these, methylene blue is extremely unreliable, while indigo-carmine is a decided improvement. Its chief use is to determine the site of the ureteral orifices in difficult cases; it will never, however, replace catheterization. Finally, phlorizin has been recommended, since a diseased kidney is not supposed to discharge sugar after injection of 0.01 gme. It seems, however, that the excretion of phlorizin sugar takes place chiefly in the glomeruli so that it is quite possible to get a saccharine urine where the nephritis affects principally the convoluted tubules. Another source of error arises if the catheter incites a reflex polyuria; the urine from the healthy side may then contain less sugar than that from the diseased side. The total amount of sugar excreted from each side cannot always be determined, hence it is best to place sole reliance upon the time which elapses before the first trace of sugar appears. Normally, this occurs in twelve to fifteen minutes; twenty to thirty minutes signify a reparable disturbance and later than thirty minutes, complete loss of function which would contraindicate nephrectomy. The appearance of sugar in twelve to fifteen minutes will prove that the kidney is perfectly healthy, provided that albumin and casts are not present in the urine. In the latter case a tubular nephritis may yet be present. There are a few cases on record where even these conservative rules have misled. The author finally concludes that only the indigo-carmine and the phlorizin tests possess some value in determining the functional activity of the kidneys.

THERAPEUTICS.

The Therapeutic Art.—O. T. OSBORNE (*Journal A. M. A.*, May 13) remarks on the deficiencies of textbooks and of the ordinary methods of teaching therapeutics and the embarrassments of the newly fledged physician in adapting his treatment to his case, and points out what seems to him the remedy. He would have laboratory pharmacology taught by a purely scientific man and the therapeutic application by a purely practical man, but would have the two courses so interwoven as to constitute one department. He lays down a program of the course of teaching, which can, of course, be improved on, he says, as the plant grows. Early in the second year he would begin with a practical experimental course in the pharmacologic laboratory, following this in succession with laboratory courses on toxicology and pharmacy. After this comes the introduction to materia medica and prescription writing, the size of doses, the recognition of crude drugs, etc. At the end of the year a written examination on all the subjects covered in the previous studies is required. During the summer vacation he would have the student spend fifty hours in the prescription department of some drug store, thus beginning a practical acquaintance with these tools of his profession. At the beginning of the third year the physiologic action of drugs is taken up and the last third of the year is devoted to lectures on appliances, applications, hydrotherapy, climatology, electricity, organic extracts, etc., and blackboard work on prescription writing and criticisng is continued daily throughout the year. Toward the end of the year lectures are given on the history of medicine with special reference to the advances in scientific therapy. In the fourth year the study of therapeutics is continued by lectures on the management of the various diseases, how to treat them with reference to the physiologic, pathologic, etiologic, symptomatologic and other considerations involved, selection and administration of drugs, etc. Throughout this senior year two clinical lectures are given each week, and the senior students act as clinical assistants in the dispensary, taking histories and writing prescriptions under dictation. At the end of this course, after passing a written examination, the graduate, Dr. Osborne remarks, ought to know something of this subject.

Treatment of Hay-Fever.—A. DENKER (*Münch. med. Woch.*, May 9, 1905) has had no success with the antitoxin treatment of hay-fever, but recommends nasal massage. The mucous membrane of the nose is thoroughly anesthetized with cocaine and adrenalin, then gentle massage is begun at the inferior turbinated bone with a cotton-carrier, dipped in a 10 per cent. solution of europhen in oil. After the lateral portions of the nose have all been treated, the massage is continued downward along the septum. The procedure should

take two to three minutes at first, later, when the mucous membrane has become less irritable, three to four minutes. The effect is marked and lasting, and in several cases there was no return of the affection during the second year.

Albumin Digestion in the Stomach.—In the hopes of obtaining some idea of the actual digestive powers of the stomach, E. Rosenberg (*Zeitsch. f. klin. Med.*, Vol. 56, Nos. 5 and 6) gave test-meals of plasmon to a large number of patients and then analyzed the various proteids found in the expression after forty-five minutes. The degree of peptonization varied within very wide limits, thus in one case of simple, uncomplicated subacidity, 61 per cent. of the plasmon was dissolved, while the lowest figure—13 per cent.—was found in an anacid gastritis. It is impossible to lay down definite rules for the different pathological conditions of the chomach except in atony and ectasy, where the average is quite constantly 26 per cent. and in hyperacidity, where about 18 per cent. is the rule. It seems strange that peptonization should be so slight in hyperacidity and often relatvely good (55 per cent.) in such serious disturbances as carcinoma. The method therefore has no more practical value than the tryptophan reaction, which was also found positive in many different conditions, and often negative in carcinoma.

The Therapeutic Use of the X-rays.—First referring to his earlier articles on the subject, W. A. Pusey (*Journal A. M. A.*, May 13) the results of his later experience with the X-ray. In some disorders, such as hypertrichosis and lupus erythematosus, the results have not equaled expectations; in some others, such as tuberculous glands and joints and deep sinuses, the results have been variable, though with some marked successes. The value of the X-rays has been most markedly demonstrated in sycosis, tinea, acne, rosacea, lupus vulgaris, blastomycosis, cutaneous carcinomata and senile keratoses. The value of the X-rays has also been shown in hyperidrosis, inflammatory dermatoses, pruritus, nevi, keloid, sarcoma and as a prophylactic after operation for malignant disease. In some other conditions, abdominal tuberculosis, acinomycosis, mixed tumors of the parotid, there has been apparent benefit from the X-rays, but Pusey does not feel inclined, from his experience, to make any very positive generalizations. In the deeper situated cancers, as might be expected, the treatment is less hopeful, though palliation may be hoped for and some surprisingly good results are reported. In conclusion, Dr. Pusey gives his latest experience with pseudoleucemia, leucemia and goiter. In the former he has repeatedly seen clearing up of the glands, but in the only case he has been able to follow up there have been repeated recurrences. In true leucemia he has seen like good effects as regards disappearance of the enlarged glands, but generally without any corresponding improvement in the condition of the blood. One remarkably successful apparent cure is reported, the blood examination revealing normal conditions and the patient apparently well. In some small parenchymatous goiters he has seen reduction in size of the tumor, but in most of his cases no benefit was observed.

Relation of School Methods to School Diseases.—W. J. Herdman and J. H. McBride reported for the committee appointed at the New Orleans session of the American Medical Association (*Journal A. M. A*, April 15). They gave an account of what has been done here and abroad in the way of school inspection and isolation of diseased children and general sanitation of school buildings, the special care of backward children, etc. They find the work satisfactorily done in a few places, though as yet inspection methods are far from complete in most communities, and in some they have never been tried. The report recommends that the American Medical Association put itself on record as urging complete and systematic medical inspection of schools and school children: "1. In the interests of the public, since it is a potent means for detecting and preventing the spread of contagious and infectious diseases; 2, for the purpose of securing to the child, while in attendance on school, the most favorable hygienic and sanitary conditions; 3, for the purpose of securing exact knowledge regarding the physical and mental capacities of each child, in order that the methods of instruction may be intelligently directed to meet individual needs."

PRESCRIPTION HINTS.

Ointment for Burns.—In his practice Professor Reclus, of Paris, France, employs for wounds of all kinds and burns a salve which combines a threefold action—antiseptic, analgesic, and hemostatic. This ointment is based on the principle that wounds, burns, or ulcerations of every kind can be painful, can bleed, and can become infected. An application in order to be of service should combat all these complications. His idea was consequently to combine, in the same vehicle, vaselin, antiseptic, analgesic, and hemostatic substances. The following preparation may be used in every case when the skin is broken, either from wounds, sores, ulcers, burns, etc. It is especially useful in the extensive wounds observed in crushed limbs.

℞ Antipyrin 5i
Boric acid ..... } aa 3½
Salol ..... }
Iodoform ..... } aa gr. xv
Phenic acid ..... }
Corrosive sublimate .....gr. ii
Vaselin 5vii

M. After washing the raw surface with hot water (130° F.), to remove all foreign bodies and destroy the microbes, the parts are sprayed with peroxide of hydrogen and the ointment is applied to all the surface on antiseptic gauze and the parts put up in absorbent cotton. The ointment, on account of the iodoform, might inconvenience some patients by its penetrating odor; in that case iodol may be substituted. Where large ulcerations are to be treated or extensive burns, the amount of vaselin might be increased two or threefold, but the doses of the active substances should remain the same.

For Leucorrhea.—If the discharge is watery the following formula will supply a valuable suppository for leucorrhea:

℞ Hydrastininæ hydrochloratis .....gr. xii
Zinci boratis .....gr. xii
Extracti belladonnæ .....gr. iii
Boroglycerini 5iv

M. Fiant suppositoria No. xii.

Sig. Introduce suppository into vagina at bedtime, after using a cleansing douche.

Enteralgia.—

℞ Spiritus ammoniæ aromatici 5i
Spiritus chloroformi 5i
Spiritus camphoræ 5ii
Tincturæ hyoscyami 5iv
Extracti cannabis Indicæ fluidi 5i
Tincturæ cardamomi compositæ ....q.s. ad. 5vi

M. Sig. Two teaspoonfuls in water every hour or two until pain is relieved.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 15, 1905.

AMERICAN MEDICAL ASSOCIATION AT PORTLAND.

IN spite of the distance from the center of population there has been a notable gathering of the members of the medical profession of this country at Portland during the past week. Nearly two thousand members of the Association registered and there were many more non-members present at this session than usual. This year's meeting will help in an important degree in extending the influence of the national body. Not only did physicians all over the country take advantage of this opportunity of being present at the exposition of the nation's medical work, but nearly every member of the Association brought with him his wife or sister or child, to enjoy a visit to the Pacific Coast and the Northwest. The trips before and after the meeting to Yellowstone Park, to the Yosemite, to Canada and to Alaska, as well as the Lewis and Clark Exposition in Portland, formed an irresistible combination which perfect weather made possible for all to enjoy. This proverbially charming summer weather of Oregon had been overdoing itself, for the week before the meeting had been a record breaker in temperature in Oregon. So much so that in Portland the iron drawbridges "froze" tight from the heat—proper allowance not having been made for expansion resulting from such unusual heat—and it was only after the fire-boats had cooled the iron girders that the draws could be moved. But by the time the bridge opened and the hot wave had reached the Eastern States, Portland weather was itself again, with clear blue skies, Pacific breezes and cool nights.

The Lewis and Clark Exposition, with its natural vistas of water and woodland and its wealth of surrounding blossoms, is perhaps more satisfactory than any of the preceding national expositions, in that it is small and thoroughly artistic, and that it represents the idea of progress rather than competition. It shows the great resources and industries of the West in a way that is more stimulating to the mind of scientific bent than other more commercial expositions. The buildings of the Exposition, as well as many of the houses of Portland, were thrown open to the members of the Association and their friends, for fêtes and receptions, and after the business of the meeting was finished the Association and its friends devoted the whole of Friday to a trip on the Columbia River with its panorama of white-capped mountains and an elucidation of salmon fisheries as a diversion. Under these circumstances it is not surprising that the social features of this year's meeting of the American Medical Association are sure to leave pleasant memories for many years to come for all those who were in attendance. Western hospitality proves its right to a place in tradition beside that of the South, and will not soon be forgotten by those who had the privilege of enjoying it.

The scientific side of the meeting was fully up to the standard of the Association's annual sessions, and was, if anything, more practical and helpfully suggestive than usual. The symposium on nephritis on Wednesday morning and that on the stomach on Thursday morning summarized succinctly recent progress as regards the diagnosis and treatment of the diseases of these most important organs. There was not a single paper contributed to these discussions that could be considered in any sense the conventional review of well-known details that such papers sometimes prove to be. Each represented an interesting phase of recent experience and study, presented by an investigator keenly alive to the advance of medicine along this particular line.

The readers of the MEDICAL NEWS when they see the society proceedings during the next few

weeks will, we feel, be as much impressed as those who were present with the fact that the discussions in the symposiums were as thoroughly scientific as those in the best European medical societies, and that they indicated a striving for ideals which will undoubtedly raise the standard of medical society work. The review of recent progress in our knowledge of nephritis proved especially interesting and timely. There was a radical departure from some of the old lines of thought and long accepted notions. It is now acknowledged that albumin and casts may both be present in the urine under certain circumstances without necessarily signifying the existence of nephritis. On the other hand nephritis of marked degree may exist without either albumin or casts being present in the urine at certain times and even for prolonged periods. Urinary examinations alone do not suffice for the diagnosis of Bright's disease, but the complete round of the patient's symptoms must be taken into consideration. When the heart fails, then it is that the kidney lesion becomes most significant and tends to presage a fatal termination. At all times the heart and arteries are most important factors, and interstitial nephritis is a local manifestation of arteriosclerosis rather than an example of true nephritis.

It was curious to note that in spite of all the detailed pathological work that has been done on kidneys during the last quarter of a century, the classification of kidney disease oftenest referred to in this symposium was that oldest of all, the large white kidney and the small and the large red kidney. The best authorities are agreed that the distinctions between kidney conditions must be made on the basis of clinical rather than pathological knowledge, and that only when our acquaintance with etiology advances much farther than at present can a definite classification be made.

With reference to treatment, two different elements were considered most important. In chronic nephritis the patient's nutrition must be maintained and too much liquid must not be advised, as this only overworks the heart without compensating advantage. In acute nephritis, starvation is the indication, as it gives the kidney as nearly a complete rest as possible; in the acute exacerbations of chronic nephritis the same rule must hold as far as the patient's strength will permit. Here great care is required. Undoubtedly more harm than good has been done in the past by too great a limitation of the diet.

The emaciation so commonly seen in nephritis is more often the result of too strict diet than effect of the kidney lesion. It was emphasized that the dietetic distinction between red and white meats usually made has no justification in their respective effects, and that the maxim of exclusive milk diet for kidney disease has done more to lower resistive vitality than to save the kidney from irritation.

In the Section on Surgery and Anatomy the series of contributions on ulcer of the stomach and duodenum, practically constituting a symposium, made it clear that the same enterprising American surgical efforts that have in recent years served to save so many lives of sufferers from appendicitis and cholelithiasis are now to prevent the serious, sometimes even fatal, complications of gastric and duodenal ulcer and at the same time forestall the development of malignant disease which so often proves the terminal stage of these disorders. Furthermore, the surgical contributions to this session on cancer have a more hopeful aspect than has been the case in recent years. Forty per cent. of patients operated upon for cancer of the breast by the radical method were reported as alive after the three-year limit, and the immunity to recurrences has increased in exact proportion to the amount of tissue removed at the primary operation. Gallstone surgery received the usual attention that it has claimed in recent years, and the evidence of progress is clear here as elsewhere. Refinements in the clinic were especially dwelt upon.

The subject of the occurrence of parasites in various parts of the United States and its recently acquired tropical possessions furnished material of special attention. The review of recent work on amebic dysentery accomplished in the Philippines shows that this disease is at last yielding the solution of many of its complex problems to American industry and genius for investigation.

Dr. Cabot paid a well-deserved tribute in the medical section to the work of American physicians that in Cuba has freed the island from the scourge of yellow fever so long epidemic, and in Porto Rico is gradually freeing, though with quite as assured effectiveness, the inhabitants of the island from uncinariasis, the cause of the anemia, which has proved such a drawback to progress.

Too much praise cannot be accorded to the workers of the marine hospital service, to the

military surgeons, and, above all, to the private investigators who have helped in the brilliant results. It has sometimes been said slurringly by our European colleagues that little that was original came from America, but these last few years show that with due opportunities and incentive for original investigation the talent is not only not lacking, but exists in a very remarkable degree.

From many sections there came, with abundant evidence of intense feeling, a cry for the reform of the patent medicine evil. It was no thoughtless bickering, but a moderate, strong, and healthy demand that the unbearable conditions as they are now found in the United States be modified. And there is good prospect that the hopes expressed will be realized, for in the frank realization that we as physicians are largely responsible for the situation lies a way out of the difficulty. Modern pharmaceutical quackery is born of modern therapeutic nihilism. Many of our leaders in therapeutics, imbued with exclusive laboratory ideals, have left their students to stumble in the darkest ignorance of their materia medica. We may honor the teachers' convictions regarding the worthlessness of much that has been passed down to us from Dioscorides to the modern herb doctor, but to ignore totally the teachings of materia medica, of prescription writing and of simple compounding has been to send forth a generation of physicians who must needs permit the pharmaceutical houses to do their thinking for them. The recognition of our shortcomings in this branch of medicine happily opens the door that may release us from an intolerable situation.

The House of Delegates conducted an immense amount of practicable business. It has proved its value as a legislative body, and the former tedious modes of transacting the business of the Association fortunately are relegated to the past. One important step in the direction of the organization of the profession throughout the country was taken when the trustees were empowered to proceed with the compilation of a medical directory of all the States of the Union.

A very interesting difference in the present meeting from all recent ones was the interest in the Sections of General Medicine and Surgery, and the comparative neglect of other sections. Many of the specialists whose faces are familiar at meetings of the Association were missed, but, on the other hand, the rank and file of the general medical practitioners of the Middle and Pacific West were better represented than ever before. Though the medical and surgical sections met in large rooms, it was impossible to seat all who came, and many stood throughout the sessions. There has probably never been so much interest displayed in the proceedings of the sections as at the present session. The interest was of the active kind that constantly catches points made, and the sessions became postgraduate teaching of the most valuable variety. It is evident that the recent meeting of the American Medical Association will long be remembered by many who have not had for years the chance to be in touch with it.

COMPLETE MEDICAL RECONCILIATION.

AT the last meeting of the Erie County Medical Society of New York State, Dr. Henry R. Hopkins, as chairman of the Legislative Committee of the Society, offered a resolution to the effect that "this organization authorize its legislative committee to prepare a bill for the purpose of improving our system of State medical examinations by creating a single medical examining board of such number of members so selected as shall be determined by the various representatives of the medical profession and instruct its committee to invite conferences with other societies, State and County, to the end that the proposed bill may meet the views and have the support of the medical profession of the State of New York." This resolution was unanimously adopted. If it could be made effective, it would at once do away, let us hope forever, with all the differing schools of practice of medicine in New York State and there would no longer be homeopath nor regular, nor eclectic, but only physicians licensed to practice in New York State.

This resolution came as a result of the discussion in the Erie County Medical Society of the extremely narrow margin (only one vote) by which the bill granting to osteopathists a medical examining board of their own and all the rights to practice medicine that would accrue to applicants from the obtaining of a license from this board. Under the present system of division of the different schools of practice as pointed out by Dr. Hopkins, the medical profession is placed in a very unfavorable position for preventing the passage of laws that might create further medical examining boards. It is true that what the osteopathists ask is to have a board all their

own so as to secure their license on the easiest possible terms, while the other schools have only the permission to select a special examination in therapeutics, but must pass in all other departments. Unless a distinct modification shall somehow be secured in the present medical status of legal qualification in New York, there is no doubt that each year the battle in the legislature against osteopathy will have to be fought over again and there is a haunting premonition that some time or other—such are the alluring ways of the osteopathists with our legislators—the necessary number of votes will be obtained and a great wrong perpetrated upon the people of this State, a wrong which it will be practically impossible ever entirely to correct.

The question occurs then: Is it possible to make the modification in the present laws suggested by Dr. Hopkins' resolution and unanimously approved by the Erie County Medical Society? In this matter it must not be forgotten that Dr. Hopkins himself is a man of large experience and thoroughly conservative judgment with regard to legislative matters and the general interests of the profession in this State. The Erie County Medical Society, practically the Medical Society of the City of Buffalo, is not apt to give its unanimous approval to a resolution that would be either impossible to fulfilment or be likely in any way to oppose the best interests of the medical profession of New York State. It is clear then that the subject may be considered one, not only open for discussion, but really demanding professional consideration at the present time.

The Medical News has more than once voiced the growing sentiment that there is at the present moment much less of real difference of opinion between the different schools of the practice of medicine than is usually thought by those not familiar with the trend of thought outside of their own special medical interests. It is with regard to therapeutics that the only differences remain. There is a general agreement of minds at the present time that this is where all the schools of medicine are weakest. Recent improvements in specific therapeutics, such as the use of the various antitoxins that have a recognized curative value, are accepted by all the schools. There seems to be ample room for the thought that there might well be a still nearer approximation and that even in the department of therapeutics the State Medical Examiners could so arrange questions that no one of the three schools of medicine would feel aggrieved because of any neglect of what is true in their special system or because of any demand beyond what their students should be expected to know.

This amelioration of present conditions could come nowhere more appropriately than in New York State. It was in this State that first of all, in order to secure the passage of a law regulating the practice of medicine, physicians of the regular school consented to lay aside some of their prejudices and work in harmony with professional brethren of the other schools in order to secure the requisite legislation. Following their example, other States did the same thing, and as a consequence, most of them now have laws for the regulation of medical practice which would not have been passed for many years perhaps except for this example of yielding somewhat in order to secure a noteworthy benefit. This movement for reconciliation could not come more opportunely than at the present time, since there is little doubt that this year is to see the reunion of the divided medical organizations of the regular school in this State. Next year will be celebrated the centenary of the passage of the first law regulating the practice of medicine in the State of New York. It would indeed be a very worthy feature of that celebration if there should be proclaimed an obliteration of the party lines in therapeutics that have been holding members of the medical profession apart. This second example on the part of New York State would be followed even more rapidly by other States to the great benefit of medical practice and professional life throughout the country.

All of this can be accomplished without any yielding of principle, but only by a rational accommodation of opinions. As we have said, the material difference is in the matter of the use of drugs, and here it is that all the schools are weakest and are ready to confess more and more as time goes on that their knowledge is obscured by ignorance and by too confident trusting in experiences made under circumstances that often suggested conclusions without really demonstrating them. The Erie County Medical Society has our heartiest congratulations in the movement it has so opportunely initiated, and we ask for it the cooperation of other county medical societies throughout the State and eventually of the State medical organizations—regular, homeopathic and eclectic. Here is a work worthy of the best efforts of a distinguished liberal profession.

ECHOES AND NEWS.

NEW YORK.

Hospitals Crowded.—During the hot days of the past week nurses and physicians at Bellevue, Gouverneur, Roosevelt, and, indeed, all of the great hospitals, were overcrowded caring for the heat cases. Patients were sent home as soon as revived, wherever this was possible, the emergency wards being crowded. It was estimated that upward of two hundred beds were almost continuously occupied by heat prostration patients in the hospitals of Manhattan alone.

Health Expert Arrested.—Eugene Christian was a prisoner before Magistrate Breen, in the Jefferson Market Police Court, on July 7, charged with having practised medicine without a license. The arrest was caused by detectives employed by the New York County Medical Society. Christian seems to have advertised rather extensively in the better class of magazines as a "naturalist and food expert." According to the detectives, the man would make a diagnosis of each case, and prescribe his own prepared health foods for the patients, as well as suggest proper exercise. The defendant in the case is said to be an author, having written several books on the subject of "How to Eat," some of which are used in the colleges and universities of this country. Mr. Gardenhire, who appeared for the food expert, said: "Mr. Christian never made any effort to practice medicine." The defendant himself said: "I did what a swimming instructor or an athletic instructor would do, gave advice along a special line, in this case as to 'How to eat.' I am sure I violated no law in what I did do."

Work of German Hospital.—The German Hospital and Dispensary, of whose advisory committee Carl Schurz is president, received bequests amounting to $16,986.80 during the last year, says the annual report, just received. Beds were endowed by Julius Heimann, Herman Sielken, and George Ehret. The number of patients treated was 3,832, and 1,854 surgical operations were performed. The cured and improved patients were 85.67 per cent., while 9.07 per cent. died. Of those admitted, 1,647 were natives of Germany and 1,200 of the United States. The classified list shows that the patients included 131 bakers, 784 housewives, 183 laborers, 214 schoolboys, 123 schoolgirls, 143 servants, and 159 small children, these being the only classes represented by more than 100 each. The principal causes of death were chronic nephritis, 28; lobar pneumonia and myocarditis, 13 each; chronic endocarditis, carcinoma of the stomach, acute appendicitis, and carcinoma of the bladder, 9 each. The institution has cared for 987,959 patients since 1857. Since 1866 the bequests have amounted to $478,008.26. Last year was the first in which the hospital and dispensary were managed under the new charter and by-laws, with the board of trustees in complete charge.

Floating Hospital's Trip.—The floating hospital of St. John's Guild, Helen C. Juilliard, made her first trip of the season on July 6, leaving the pier at the foot of West Fiftieth Street, and making landing at West Thirty-fifth Street and West Tenth Street. Three hundred and thirty-six mothers and children were taken for a sail on the waters of the bay. From now on throughout the summer the hospital will make trips daily except Sunday, and when the weather is stormy. On Mondays and Wednesdays the hospital will land at North River points, as above. On Thursdays and Saturdays it will make landings along the East River—at the foot of Twenty-fourth Street, leaving at 8 A.M.; foot of Third Street, leaving at 8.30 A.M.; and Market Street, at 9 A.M. On Tuesdays and Fridays the hospital will leave the foot of East Twenty-fourth Street, Manhattan, at 7.30 A.M., and then make landings at Brooklyn points, as follows: North Second Street, 8 A.M.; Hudson Avenue, 8.30 A.M.; Hamilton Avenue, 9 A.M. The general plan of previous seasons will be followed. The infants will be given their feedings as required. The other children will be given milk to drink during the morning, and again in the afternoon, and the adults and older children will be furnished with a hot meal at noontime. Tickets of admission to the hospital are distributed at nearly 1,500 points throughout the city, including all the prominent hospitals, dispensaries, diet kitchens, day nurseries, missions, many doctors and druggists, and by individuals. Tickets for distribution can be had by applying to the general agent, at No. 501 Fifth Avenue, New York. The floating hospital has been thoroughly equipped under the new regulations of the United States Steamboat Inspection Service, and has a complete fire-fighting apparatus, 1,624 life preservers, life rafts, life boats, and life buoys.

Work on New Bellevue Hospital Soon to Begin.—The construction of the first section of the new Bellevue Hospital is to begin in a few weeks. The first section, to be known as the southern wing, will consist of two pavilions seven stories high. Each will be 150 feet long and 36 feet wide. They will inclose a court 64 feet wide on two sides. The sum of $850,000—one-tenth of the estimated cost of the entire structure—was appropriated by the Board of Estimate and Apportionment, to start the work, and this amount is now available for the erection of the southern wing. The new Bellevue will occupy the site of the old institution. The boundaries of the hospital grounds are Twenty-sixth and Twenty-eighth streets, First Avenue and the East River. The hospital was founded in 1816, but the greater part of the present institution was completed in 1855. The old hospital is always overcrowded, and is lacking in many facilities necessary to an ideal modern hospital. McKim, Mead & White, the architects, originally planned a new structure to cost $11,900,000, but the plans were modified later without sacrifice to capacity or convenience. The two new pavilions of the southern wing are to be connected at their western extremities by a seven-story administration building. The eastern extremities are to be joined by open three-story arches. "Sun rooms" and open balconies and roof gardens are to be special features of the institution. The experience of the past few years in building hospitals throughout the world has demonstrated the value of this adjunct to medical treatment. There will be sufficient balcony space to accommodate all the patients of all the wards. One ward in the southern wing will be devoted exclusively to the care of consumptive patients. The purpose of the Board of Trustees is to build at the rate of $1,000,000 a year, tearing down sections of the old buildings as the work proceeds.

Hospital Doctors Hurt.—Accidents to ambulance surgeons are becoming positively epidemic in New York, at the rate of two a week. On the afternoon of the Fourth an ambulance from the Hudson Street Hospital was struck and overturned by a Sixth Ave-

nue car, at Reade and Centre streets. Dr. T. Harris Cherry was hurled from the ambulance ten feet, into a group of women, children and lunch baskets waiting for a car at the corner. He was taken unconscious to the hospital, where it was found he was suffering from concussion of the brain, two severe scalp wounds and three broken ribs. Fears were entertained at first that he might not recover, but at last account he was doing well. On July 7 the ambulance of the Seney Hospital, in Broklyn, while responding to a call from a shipyard in the Erie Basin, was upset by a collision with a trolley car, and its three occupants, two doctors and the driver, were hurled to the street. The accident occurred in Third Avenue and Fourteenth Street, the ambulance reaching that point simultaneously with a trolley car bound for Bay Ridge. The ambulance horse dashed into the side of the car and the ambulance turned upside down several yards away. Dr. A. C. Hutcheson, the ambulance surgeon; Dr. Wilson B. Zimmer, a member of the hospital staff, and the driver, Charles Parker, all struck on their heads some distance from the wreck. The victims were picked up, the young doctors unconscious, and carried to a drug store. Each was cut on the head and bruised on the arms. They were attended by Ambulance Surgeon Livingston, of the Norwegian Hospital, and removed to the Seney. It was found that Dr. Zimmer, who was still unconscious when he reached the hospital, had sustained concussion of the brain. The doctors said that he would recover. He is a graduate of Cornell, and has been attached to the Seney Hospital for the last six months. Dr. Hutcheson and the driver escaped with painful scalp wounds.

Pasteur Treatment of Rabies.—The New York Health Department gives the Pasteur preventive treatment for rabies at the Research Laboratory at the foot of East Sixteenth Street. In addition, the virus is sent out mixed with a preservative, to be administered by the attending physician to persons desiring to take the treatment at home. When sent from the laboratory it is mailed daily by special delivery. The results of treatment given by the latter method have been as satisfactory as when administered at the laboratory, but it is considered advisable that not more than two days should elapse between the mailing of the virus and its injection into the patient. The course of treatment lasts from two to three weeks. It is strongly recommended that wounds inflicted by rabid or suspected animals be thoroughly cauterized with fuming nitric acid, or, if this is impossible, with the actual cautery. Immediately washing out of the wound is also advisable. When possible, it is recommended that animals suspected of rabies be securely chained and kept under observation for eight days. If rabies exists, symptoms will develop so that a definite diagnosis is possible within this time. If the animal is killed the carcass may be sent to the laboratory for diagnosis. The routine is to make an examination of smears and stained sections of the brain tissue, and also to make animal inoculations. By the former method a positive diagnosis may be reached in from thirty-six to forty-eight hours. A failure to find the characteristic lesions does not, however, exclude rabies. In the event of a failure to find the lesions, the animal inoculations are relied on for a diagnosis, which usually requires from eight to eighteen days. In sending animals from a distance it is recommended that, if small, the entire body be sent. If this is impossible, the head alone should be sent. The animal or head should be securely fastened in a box, and packed with a considerable quantity of ice and sawdust; the whole to be shipped to the laboratory in a larger box.

PHILADELPHIA.

Appointments.—Recently several changes in the Germantown Hospital staff were announced. Dr. John Hedges and Dr. William K. Muller were made chiefs of the medical department, and Dr. Samuel Rhoads was made assistant chief.

"Headache Powders" Fatal.—The depressing effects of the coal-tar products are illustrated in the death of a lady who, in attempting to get relief from the headache she had been suffering with for several months, took two "headache powders" and died soon afterward.

"Four-Day Fever."—The physicians at Coledale, a town in the eastern part of Pennsylvania, are puzzled by the appearance of a strange disease, which, from its rapid spread, seems to be contagious. It begins with violent headache, followed by high fever, which lasts four days. In some cases the skin is covered with red blotches. Altogether ninety-three cases have been reported, but no deaths.

Railroad Medical Examiners to Aid Dr. Dixon.—Following is a list of the examiners of the two roads appointed by Dr. Dixon as inspectors: Pennsylvania Railroad—Dr. Samuel W. Latta, Philadelphia, chief; D. W. Nead, C. J. Roberts, E. C. Town, J. L. Bower, Reading; J. L. Wright, Columbia; W. T. Bishop, York; S. M. Crawford, Harrisburg; A. T. Poffenberger, Sunbury; H. E. Westhaeffer, Williamsport; J. B. Lincoln, Renovo; S. A. Bonnaffon, Erie; R. B. Moore, Huntingdon; H. W. Pownall, Tyrone; W. B. Diefenderfer, Altoona; C. F. Hough, Cresson; C. W. Banks, Derry; D. M. Easter, Youngwood; W. K. T. Sahm, Pittsburg; J. B Hillman, Pitcairn; J. C. Lemmer, Oil City. Reading Railway—Dr. Casper Morris, chief. District No. 1, office, Columbia Avenue Station; F. E. Brister, Francis S. Ferris, Norris S. McDowell. District No. 2, Reading: Charles A. F. Detweiler, Albert F. Bronson. District No. 3, Pottsville: Thomas F. Heebner. District No. 4, Tamaqua: William H. Brothers.

Dr. Samuel W. Latta informed Dr. Dixon that each car, containing a case of any contagious disease, was fumigated, the inner surfaces washed down with bichloride solution, and allowed to stand with windows raised for twelve hours. Dr. Casper Morris stated that similar precautions were taken on the Philadelphia and Reading Road.

CHICAGO.

Chicago's New Medical Magazine.—*Surgery, Gynecology and Obstetrics*, a new international magazine of surgery, edited by a staff of the most eminent surgeons and physicians, made its first appearance in Chicago this week. This new publication will be issued monthly, and is the only one of its kind in the West, and one of but three in the entire country. Dr. Franklin H. Martin is managing editor, and Dr. Allen B. Kanavel associate editor. The other members of the regular editorial staff are: Drs. John B. Murphy, E. Wyllys Andrews, F. A. Besley, C. S. Bacon, Rudolph W. Holmes, Nicholas Senn, J. Clarence Webster, E. C. Dudley, John C. Hollister, William R. Cubbins, and C. V. Bachelle.

Comparison of Death-Rate for First Six Months of 1905 With Same Period of 1904.—At the close of of the first six months of the year it may be pre-

dicted, with a fair degree of certainty, that 1905 will establish a new record for the healthfulness of Chicago. This prediction is based on the fact that the average annual death rate of the first six months of each year during the ten years, 1895-1904 inclusive, was 15.51 per 1,000 of population. For the last six months of each year the average was 14.43, or 7.48 per cent. lower. The rate of the first six months of 1905 is 14.09—the total deaths being 13,918. If the second six months should be 7.48 per cent. lower than the first six months its rate will be 13.04, the total deaths for the year about 26,800, and the annual rate for 1905 will be 13.56—the lowest ever recorded for Chicago. The lowest previous was 13.88 per 1,000 in 1901—a year of unusual healthfulness throughout the world. While there were 224 fewer deaths from all causes and at all ages, 672 fewer between the ages of five and sixty years, and 445 fewer over sixty years than in the corresponding period of 1904, there were 894 more deaths under five years of age. Of this excess less than 50 per cent. is accounted for by the unusual prevalence of some of the contagious diseases of infancy and childhood—most markedly measles and whooping cough. There were 185 deaths from measles, or 169 more than last year, and 258 more from whooping-cough, or 237 more than last year. An examination of the records shows that of the remaining 50 per cent. excess of under-five-year deaths, a certain share is due to an unusual proportion of deaths at this age period from the acute intestinal diseases, from bronchitis and from pneumonia. While the first two show increases of only 31 and 20 respectively and pneumonia shows a decrease of 563, the number of deaths from these diseases among children was much greater than last year. For the rest, an increase in the developmental affections of infancy—premature birth, injuries at birth, congenital debility, heart defects, etc.—is responsible. Compared with last year the death-rates of cancer, consumption and diphtheria are substantially unchanged; pneumonia is 12.4 per cent. less; nervous diseases, 22 per cent. less; typhoid fever, 27 per cent. less, and scarlet fever 63 per cent. less. Suicides increased 55 per cent.

CANADA.

Medical Matters in Hamilton, Ont.—Owing to disagreement with the Board of Trustees of the Hamilton General Hospital, Dr. Freeman, the medical superintendent, resigned, Dr. Walter Langrill, the Medical Health Officer, succeeding him, and Dr. Roberts, of Hamilton, succeeding Dr. Langrill.

Few Insane Now in Ontario Jails.—Dr. R. W. Bruce Smith, Inspector of Asylums and Prisons for Ontario, has just completed a tour of inspection of the institutions in the eastern part of the province, and reports that there are very few insane people confined in the common jails in that part of Ontario. In the Toronto jail there were at this time last year no less than thirty-six lunatics, while at the present time there are but three.

Dominion Aid to Consumption Sanitaria.—The joint committee of the Senate and House of Commons of Canada, to consider measures for checking the spread of tuberculosis met on July 6, at Ottawa, and appointed a subcommittee to devise plans to reach the Government. It was the consensus of opinion of the members of both houses present, that the Government should make a substantial grant toward the work of erecting sanitaria in different parts of the Dominion.

Manitoba Medical College, Winnipeg.—The annual calendar of the Manitoba Medical College makes some important announcements, chief of which is that operations have commenced on a new building adjacent to the Winnipeg General Hospital. The faculty has also been enlarged to a total of twenty-nine members by the addition of the following practitioners of Winnipeg: Drs. A. J. Douglas, O. Bjornsen, G. Hiebert, C. C. Field, W. Rogers, H. Mackay, S. J. Elkin, A. J. Burridge, and W. Webster. The five-year course has also been adopted. The new college building will afford accommodation for all branches of medical study for many years to come.

Annual Report of the Royal Jubilee Hospital, Victoria, B. C.—The fifteenth annual meeting of the Board of Directors of the Provincial Royal Jubilee Hospital of Victoria, B. C., was held during the latter part of June in that city. The chief event of the past year in connection with this hospital was the opening of the new Strathcona wing, and the most important item in view is the proposed children's ward. The number of patients treated during the last hospital year amounted to 1,058, as against 1,048 for the previous year. The total collective days' stay was 21,307 days. The daily average number of patients shows an increase of 4.43. The cost of maintenance during the year amounted to $36,294, and the daily average cost per patient was $1.70. Dr. Edward Hasell is the resident medical officer.

New Sanitaria.—A sanitarium for consumptives is to be erected near Holland, Man. The site for the Provincial Sanitorium for Consumptives of British Columbia has been chosen. It is to be at Savonna, B. C., and will first make its appearance as a canvas settlement, the patients being all housed in tents. Mr. Thomas McCormack, of London, Ont., has placed $3,500 at the disposal of the National Sanitarium Association, for the erection of a cottage on the grounds of the Muskoka Sanatorium. The Salvation Army is erecting a fine new hospital in Winnipeg, Man., to have a frontage of 150 feet. It will engage fifteen nurses and will be ready for occupancy by January next. A new wing is being added to the Western Hospital, Montreal, which, when completed, will enable this hospital to accommodate 500 patients.

Toronto Doctors Endorse New General Hospital Scheme.—"And those who came to scoff remained to pray" might be said of a gathering of Toronto physicians called together July 6, for the purpose of entering a protest against the proposed grant of $200,000 which the City Council of Toronto will give toward the erection of the new General Hospital, which is—in a large measure—to provide facilities for clinical work in connection with the medical faculty of Toronto University. It is understood that the fervent exhortations of Dr. Charles Sheard, Toronto's Medical Health Officer, were largely responsible for the conversion of the recalcitrants. After he had explained what he would recommend to the City Council, there was a great rush for the penitent bench, there being only three "doubting Thomases" left in the outer darkness. Operations will soon be gotten under way for the best equipped hospital in Canada, as there is now in sight an even million of dollars to commence with. Dr. J. W. Rowntree, of last year's house staff, has been temporarily appointed superintendent, in succession to Dr. O'Reilly, and the hospital management is advertising for a superintendent—either a business or a professional man.

Annual Meeting of the Ontario Medical Council.—The Council of the College of Physicians and Surgeons of Ontario held their annual meeting in Toronto during the past week, when the following officers were elected for the coming year: President, Dr. A. A. Macdonald, Toronto; Vice-President, Dr. W. H. Moorhouse, London; Registrar, Hon. Dr. Pyne; Treasurer, Dr. H. Wilberforce Aikins. During the course of the meeting, which took up the greater part of the week, numerous subjects of importance, both to the profession and the public, were discussed. One question discussed was that of Christian Science, the entire matter being left in the hands of the Legislative Committee, consisting of Dr. W. H. Moorhouse, London; Dr. J. L. Bray, Chatham, and Dr. Spankie, Wolfe Island, together with the Past President, the Hon. Dr. Sullivan, who will determine whether it will be wise in the interests of the profession, as well as in the interests of the public, to approach the legislature, asking for the abatement of the evil. This same committe will also place before the Government the lack of accommodation for the treatment of the consumptive poor of the province, and will ask that substantial aid be given toward municipal sanitoria. The official prosecutor reported that during the past year fifty-two cases had been dealt with, in twenty-four of which convictions had been secured, while nine left the country, eleven dismissed, and six not proceeded with. The financial statement was satisfactory, showing a reduction of the mortgage loan on the medical building of $5,000. The receipts amounted to about $35,000, and there was a balance on hand of $5,764.92, in spite of the fact that there was a good number of practitioners throughout the Province who were in arrears for their annual dues. The Property Committee reported that they had decided that at the present time it would be unwise to proceed with the sale of the building which was ordered by Council a year ago. Owing to the fact that there had been some agitation to have the annual examinations held at London, in addition to Toronto and Kingston, the solicitor was asked for his opinion of the matter, who interpreted the clause in the Ontario Medical Act to the effect that special legislation would be required from the legislature to provide for the holding of examinations at other points, as specified in the act, namely, Toronto and Kingston.

GENERAL.

Roosevelt to Doctors.—At the convention of the Association of Physicians of Long Island, held at Oyster Bay, on Wednesday, President Roosevelt delivered the principal address.

Iowa and Illinois Central District Medical Association.—The annual meeting of the Iowa and Illinois Central District Medical Association was held at Schützen Park, Davenport, Iowa, July 13.

The Fourth's Death List.—*The Chicago Tribune's* list of Fourth of July casualties throughout the country as revised on July 5, shows: Dead, 54; total injured, 3,157; by fireworks, 1,258; by cannon, 294; by firearms, 446; by gunpowder, 706; by toy pistols, 373; by runaways caused by explosions, 80. Total fire loss, $251,317.

Doctors Leave the Raybrook Hospital.—A meeting of the Board of Trustees of the State Hospital for Tuberculosis, at Raybrook, N. Y., has been called to appoint a successor to Dr. Pryor, the superintendent, who has resigned. Dr. Merriman, a member of the staff, has also resigned. Dr. Pryor will reside in Saranac Lake, where he will resume the practice of medicine.

American Pharmaceutical Association.—The fifty-third annual meeting of this association will be held at Atlantic City, N. J., September 4 to 16 inclusive. Application for membership may be sent to the Secretary of the Committee, H. M. Whelpley, 2342 Albion Place, St. Louis, Mo., up to September 1, after which date they should be sent to him in care of The Islesworth, Atlantic City, N. J.

New Jersey Bars New York Doctors.—The New Jersey State Board of Medical Examiners has decided to cease indorsing New York medical licenses for the present. This is retaliation against New York. The board's resolution says: Whereas, The educational and examining standards for the medical license of New Jersey are at least equal in all respects to those of New York and in some respects higher, and Whereas, The degree of unreasonableness in the matter of inter-State indorsement on the part of New York cannot be further ignored; therefore be it Resolved, That on and after October 16, 1905, the date of the next regular meeting of this board, the indorsement of medical licenses issued by New York will be suspended until further notice.

Railway's Ban on Doctor.—The Connecticut Railway and Lighting Company has posted on its bulletin board in Ansonia, Conn., the following notice: "Whenever you have occasion to summon a physician to attend an injured person you will please bear in mind that the company has an arrangement with most of the practising physicians of Ansonia, Derby and Shelton, to respond to emergency call. Dr. W. H. Conklin is an exception to this rule. Superintendent Beardsley." Dr. Conklin has had many railway cases, and in recent suits his testimony had weight with the court in awarding damages. The doctor has had the notices printed and mailed to the conductors and motormen because, he says, he does not wish the men to forget the rule in their excitement when an accident occurs and call him, which would jeopardize their places.

Mysterious Eye Disease in Central Africa.—The *London Mail* reports a somewhat remarkable eye disease as at present prevalent in several parts of British Central Africa, Northwestern Rhodesia, and in Portuguese Zambesia. At first it was noticed in cattle, sheep and goats, and only recently was it found to have attacked the natives. The disease is at present raging from Port Herald, a British station on the Zambesi, right on toward Tete, a distance of over 200 miles, and at this latter place it is reported to be quite an epidemic. Mr. William Arnott, a traveler, who recently returned from Tete, states that he observed hundreds who were suffering from the disease, and a large number were totally blind. One of the sights of Tete on a Sunday morning is the long lines of blind people who enter the town to beg, each line being led by a child.

Come Back Blue From Panama.—Many canal employees were among the sixty cabin passengers who arrived on July 5 from Colon aboard the Panama Railroad's steamship Advance. They took a pessimistic view of the sanitary situation on the Isthmus. Some declared that not more than 10 per cent. of those who were needed by the Government in clerical work were able to attend to their duties, and that many more cases of yellow fever existed than were officially reported. Aboard the Advance was the body of Samuel Hirsh, who died of yellow fever in Panama. Three passengers by the Advance were detained and sent to Hoffman Island for observation because they had unusually high temperatures. They are George Baylor, an en-

ginger on one of the boats of the Canal Commission; Edward P. Penick, a laborer, and Frank Namact, a boilermaker.

New Superintendent for Bellevue Hospital.—Dr. Samuel T. Armstrong, medical director of the Washington Life Insurance Company, has been suggested for Superintendent of Bellevue and Allied Hospitals. It is thought that he will receive the appointment at the next meeting of the Board of Trustees. Dr. Armstrong is a native of St. Louis and received degrees from the St. Louis University and the St. Louis Medical College. For ten years he was in the United States Marine Hospital Service.

American Hospital in Turkey.—The trustees of the American Hospital and Training School for Nurses, to be established at Constantinople, Turkey, met recently and adopted plans for the establishment of the hospital. Among the trustees are Henry O. Dwight, author of "Constantinople and Its Problems," James S. H. Umsted, editor of the *Wall Street Summary;* the Rev. Charles H. Richards, the Rev. Charles H. Creegan, Ernest Abbott and Omar H. Carrington. Dr. Thomas Spees Carrington is to have charge of the hospital. He has been engaged in practice in Turkey and knows the local conditions. He will take with him several American trained nurses and they will train Turkish girls to be nurses and will go into Turkish homes and teach the mothers how to reduce the rate of infant mortality. In the past half of the Turkish babies have died in infancy and the need of a modern hospital with all the best American appliances and medicines for treating sick children is great. In the course of time an infant incubator will be added, but Dr. Carrington said yesterday that he would not take one with him on his first trip. The hospital staff will also endeavor to remove the Turkish prejudice against surgery, which now makes the practice of that profession a precarious undertaking in the Ottoman Empire. "The Turk is not as violently opposed to surgery as he once was," remarked Dr. Carrington. "If a patient dies under the knife the surgeon is no longer sewed in a bag and given a chance to swim the Hellespont. Nevertheless the surgeon whose operation is unsuccessful is liable to be made defendant in both civil and criminal actions instituted by relatives of the deceased." Checks in aid of the hospital should be made payable to Brown Bros. & Co., bankers, 59 Wall Street.

OBITUARY.

Dr. GEORGE M. SCHWEIG, who for many years was in the service of the Board of Health, died on July 5, at his home, No. 2880 Broadway, New York. He was born in Germany sixty-three years ago, and came to this country when nine years old.

Dr. H. M. STOKES, a well known physician of Philadelphia, shot himself on July 7, at his home in that city.

Prof. HERMANN NOTHNAGEL, the well known clinical authority and author of important medical works, died in Vienna on July 7. Papers were found in the professor's room in which he had described his symptoms for hours before his death, including those of three severe attacks of coma. Hermann Nothnagel was born in the Province of Brandenburg, Germany, in 1841. He was graduated from the medical school in Berlin in 1864 and immediately became a teacher, serving in Königsburg, Berlin, Breslau and Jena. He was appointed professor of clinical medicine in Vienna in 1882 and was the author of a number of well-known medical text-books, among which are "Pathology of the Nerves," "Use of Drugs," "Diagnosis of Brain Diseases," "Researches in the Physiology and Pathology of the Intestines," and a "Handbook of Medicine."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENITO-URINARY DISEASES.

Stated Meeting, held February 15, 1905.

The President, Ramon Guiteras, M.D., in the Chair.

Epithelioma of Penis, Amputation of Entire Penis, one Testicle and Two-Thirds of Scrotum with Transplantation of Urethra, Recovery.—Dr. Follen Cabot, Jr., reported the case of a German, forty-one years old, single, who had syphilis sixteen years ago, for which he had little treatment. He first saw him in the City Hospital last November. His family history was good. The disease of the penis began as a pimple under the foreskin, and in eight months had involved the whole penis in a gangrenous slough and destroyed the penile urethra. The scrotum was as large as a cocoanut, and when seen by Dr. Cabot it was filled with pus and extravasated urine. A urethral opening was made in the perineal region and two-thirds of the scrotum, all of the penis, inguinal glands, and one testicle removed. The patient made a perfect recovery, and now urinated without difficulty.

Cancer of Penis.—Dr. Follen Cabot, Jr., presented a man aged forty-seven years, who had never had intercourse in his life, and also who had never retracted his foreskin. A pimple had appeared under his foreskin which had increased in size and had extended to within one-half an inch of the pubis. He said that Dr. Lilienthal had stated that, in a large experience, he had never seen a cancer of the penis appear in a man of the Jewish race. This patient had been under observation for about one year. A small piece of the growth was removed and examined microscopically. Reported to be epithelioma. An interesting point in the case is the absence of involvement in the inguinal glands, although the disease has been present on the penis a year. The pathologist who made the examination was not perfectly satisfied with the findings because an insufficient amount of the growth was given him.

Dr. L. Bolton Bangs, after examining the patient carefully, said that there was no doubt in his mind about the diagnosis, but the condition had remained quiescent so long he did not know. He believed this man required as radical an operation as the first case reported by Dr. Cabot.

Multiple Fistulæ of the Perineum.—Dr. Ramon Guiteras presented a patient that had been shown before the Academy about five years ago. He had had an extravasation of urine following a rupture of the urethra. When he was first presented he had multiple sinuses which could not be cured at the time. His reason for presenting him was because he wished the opinion of the gentlemen present, and asked their advice regarding operative measures. The old scars were shown. When first seen he had had extravasation for forty-eight hours, and the retention of urine began with so much pressure on the tissues outside the urethra that it caused a compression of such a degree that he could not urinate and the scrotum seemed to be on the verge of gangrene. Six incisions were made and a purulent material was squeezed out, so that he had been enabled to pass a catheter into the urethra; this was left in situ and a wet dressing applied. After this the patient was able to urinate, but the sinuses developed, and, at this time, he had been presented to the Academy. One of these sinuses ran from behind the corona down beneath the testis, a distance of about six and a half inches. Some of them came through the penis and two

were in the perineum. Numerous suggestions were made regarding the treatment of the fistulæ, and, as a result, he performed a perineal section, draining the bladder, and then proceeded to treat these strictures by the injection of carbolic acid in some and iodoform emulsion in others. The long fistula, however, was the one that caused the most trouble, and which he had puzzled the most over. He threaded a probe with iodoform gauze and pulled it through, and so irritated the sinus; this was left in place for twenty-four hours and then withdrawn. This set up an adhesive inflammation and healed the fistula. There were some that did not heal and to which he applied the negative pole of a battery, and with success. The perineal wound closed and then an instrument could be passed through the urethra. A constriction took place and a second perineal operation became necessary; after that a sinus remained in the perineum. During the last two years some contraction had taken place in the cicatricial tissue, so that, when the patient urinated, with the exception of a few drops, it came from the perineum. Two months ago another operation was performed, a perineal section and an internal urethrotomy, with drainage for four or five days, and then he could pass a No. 32 soft rubber catheter through the urethra, and allowed it to remain for four weeks. When it was withdrawn the perineal wound was nearly closed. Sounds were passed for some time. Two weeks after leaving the hospital a No. 21 American sound passed readily. The urethra was still of large size, and there was a very slight fistula present. The probabilities were that it would again contract, and must be operated upon. Sounds should be frequently passed. The case was of particular interest because of its rarity and because of the fatty deposits between the areas of fibrous tissues.

Extrophy of Bladder.—Dr. Ramon Guiteras presented this patient, a strong and healthy man, who had had an extrophy about four inches in diameter. The pubes was separated at the symphysis between three and four inches, and the result was that the corpora cavernosa extended backward from the membranous or prostatic urethra to its insertion. The only thing remaining to be seen was the penis, which was in a state of hypospadias. In other words, it was simply a glans attached to the prostatic portion, without any apparent penile portion. The ejaculatory as well as the prostatic ducts could be seen. There were about twenty-four or twenty-five openings of prostatic ducts, which extended up into the prostatic follicles besides the ejaculatory ducts. The patient had suffered a great deal since childhood, and had tried a great variety of urinals, but without relief; the result was that he at all times had a leakage of urine, causing much chafing. At last he gave up trying to use any urinal, and went about with trousers continually wet. His bladder was very much inflamed, and at all times mucus could be seen on its walls as well as ulcerations. The patient wore ulsters summer and winter, which he could keep away from the irritated surface by holding his hands inside of its folds. His occupation, a blacksmith, kept his body flexed, and so the clothes were kept away from the raw surfaces. When the question of operation came up he was given the choice of a plastic operation, taking a flap from around the bladder, or a transplantation into the rectum, and it seemed to him that better results could be had by doing the plastic operation. The transplanting of the ureters into the rectum, while attended with success, caused at the same time a very irritable condition of the rectum. In time the rectum could hold a certain amount of urine, yet the urine escaping from the rectum would produce an irritation about the anus and the cleft between the nates and perineum. Again, the rectum itself might become inflamed. In these cases there usually occurred later on an extension of the inflammation up the ureters and into the pelvis of the kidney and giving rise to a pyelitis, and the patients usually died from a pyelonephritis. The operation Dr. Guiteras performed was a modification of Wood's, simply a skin flap being made, measured so as to cover the wall of the bladder. In this patient the skin of the abdomen seemed to be devoid of hair. If hair had been present electrolysis would have first been done. He brought the flap down over the bladder, freeing the edges of the skin about its circumference and the bladder, beveling both. He brought the skin flap down to the base of the bladder and sewed it there; then he took two inguinal flaps and brought them over the raw surfaces; these flaps came in contact with the new surface of the abdominal flap from the patient. Then the sides of the prostatic portion and glans which were made raw on their outer surface were brought together and sewn. The prepuce below was taken and split laterally and brought over the glans. The mucous membrane was dissected up so as to give a larger flap of raw surface of mucous membrance and prepuce, which was sewn into the bottom of the anterior flap coming down from above. Catheters were introduced into the ureters and brought out through a canal made by the plastic operation. A soft rubber catheter was also introduced into the bladder through the urethra. Dr. Ayres had charge of the case after Dr. Guiteras left, and the patient's recovery was most uneventful. In a great many of these cases a number of plastic operations have to be performed, but in this case there were but two sinuses remaining, one healing about three days after operation, and the other less than three weeks. They both healed spontaneously. The denuded area above was covered by skin grafts taken from the thighs. Without further operation the artificial bladder was able to hold urine, and he attributed this to the fact that the urethral catheter had been introduced into the ureters and, in this way, the urine had been carried directly to the outside and had not come in contact with the bladder wall. But Dr. Ayres had stated that after two days the ureteral catheters would not drain, and the soft rubber catheter was left in the bladder. He believed this was the secret of the rapid healing of the wounds in this case. There was at present no leakage, and the patient was up and about and could hold two ounces of urine while standing and more when reclining. As contraction further took place he would be able to hold more and more. Later irrigations of the bladder would be practiced, and this would tend to dilate it and make it hold more. Even if this patient lived a catheter life the result would be almost as good as if he had but slight control of the bladder. His prostate was about one-half an inch up from the anus. Before the operation one could palpate the prostate because of the absence of the pubes. Six weeks after the operation the patient experienced his first erection, which showed a beginning activity of the genital apparatus, and this he believed would be followed by even more activity of the internal genitals. When the patient was born, if the pelvis had been strapped and pressure applied, the pubic bones might have become approximated.

Dr. Martin W. Ware asked Dr. Guiteras if a microscopical examination had been made of the fatty deposits. Or was the condition not a false elephantiasis, due to an interference with the lymphatic circulation, because of the many incisions necessitated.

Dr. L. Bolton Bangs said that multiple fistulæ, due to obstructions in the urethra, should be treated by gen-

erous and radical removal of the obstruction, together with perineal drainage of the bladder of sufficient duration to satisfy the operator that all indications of infection were no longer present. With regard to the second case, he thought Dr. Guiteras was to be congratulated upon the results he had obtained. He had seen cases in which there was a minimum of separation of the pubic bones, but with loss of the structures above the pubes. They all had suffered the same. All the cases were miserable creatures and seemed to him to be degenerates in some way. Even if one succeeded in the primary operation, and the patient did not require a secondary one, much had been done for the individual, but they generally required several operations, and even then the result was not satisfactory. The last patient he attempted to operate upon he could do nothing because the patient nearly died from chloroform poisoning. This patient was a young man of considerable intelligence, but he too was a degenerate in other ways. Recently he had received a letter from his mother in which it was stated that his pusillanimous nature had disappeared, and that he had developed some of the traits of manhood, becoming more and more of a man as time went on. Dr. Bangs said he knew of no better operation in these cases than Wood's.

Dr. William K. Otis said that extrophy of the bladder was one of the most distressing affections, and although many operations had been devised for its relief the results were almost uniformly bad. Therefore, he thought Dr. Guiteras was greatly to be congratulated upon his success in this instance.

Dr. Guiteras said, in answer to Dr. Ware, that he believed there was a pseudo-elephantiasis present. He had had no microscopical examination made of the fatty deposits; they might not be fatty, but some other soft tissue. With regard to the extrophy of the bladder case the patient was operated upon less than two months ago, and he certainly thought that in such a short time the patient had made an excellent recovery, although it would require some time before the cystitis became cured.

Plastic Operation for the Cure of a Recto-Urethral Fistula.—Dr. Martin W. Ware presented this patient to show a sucessful effort in curing what is conceded to be a very bad form of fistula occurring between the rectum and urethra. The patient one year ago contracted a urethritis while in Europe, but consulted no physician. Four months later he came to this country and was shorly afterward admitted to the Mt. Sinai Hospital for the following symptoms: An intense desire to pass his urine associated with a very great deal of rectal tenesmus; there was some temperature and pain in the perineum; also a discharge from the urethra, there being both a posterior as well as an anterior urethritis. Examination revealed a very tender but not large prostate. The secretions contained gonococci. The treatment instituted four months after his attack of gonorrhea was an expectant one; he was not irrigated, but simply kept at rest in bed, and hot rectal irrigations and hot sounds used. The vesical tenesmus continued, and after one week the pains became so severe, with retention of urine, that it became necessary to use the catheter. The rise in temperature led to the suspicion of an abscess, and this was verified by rectal examination, a fluctuating point being made out. Because of a freer discharge of pus from the urethra the treatment outlined was continued a few days, but as the patient became septic it was deemed advisable to give freer vent to the pus. To verify its presence, a puncture was made into that part of the prostate which bulged into the rectum, and pus was evacuated. With a few strokes of the knife the abscess was drained by way of the perineum. As the patient was about to undergo the operation he said that he had a discharge of pus from the anus. Two weeks after healing of the perineal wound took place, but urine began to be discharged from the rectum; at first urine passed through the rectum as well as through the perineal fistula. The perineal wound was then tamponed, but a large fistulous opening in the rectum, which caused the patient great discomfort for many weeks, persisted. Nothing could be done to prevent the water being passed by way of the rectum, notwithstanding the perineal wound had closed. Perineal section was again performed, and a communication was found to exist between the membranous urethra, at a point close to the prostatic apex and the rectum. The opening in the rectum was rather a long slit and the fistula funnel-shaped, with the apex of the funnel towards the urethra. The fistula was excised, the rent in rectum sewed with Lembert sutures, and the opening in the urethra likewise, and catheter à demeure left in situ for ten days, and the bowels kept costive as long as fourteen days. Six weeks later, when he was discharged from the hospital, his urethritis still persisted. Since then an epididymitis set in and further treatment of his urethritis was deemed inadvisable. He presented this patient particularly for the reason that some years ago Dr. Tuttle had presented a case of recto-urethral fistula and emphasized the fact that nonsuccess attended any operation as a rule, and that certain difficulties were encountered which he had endeavored to overcome. He cited a number of authorities to prove how very difficult it was to cure these cases. The operation Dr. Tuttle advised, Dr. Ware believed, from a technical standpoint, to be a difficult one, and the space for manipulation was very small indeed.

Dr. Follen Cabot, Jr., said that the only case of recto-urethral fistula that had occurred in his experience followed a prostatectomy where he tore through into the rectum, the opening being the size of the end of a finger. He sewed it up at once, taking but one stitch, and no further trouble resulted. It was not, strictly speaking, in the urethra, but more in the perineal opening.

Dr. Henry G. Spooner asked whether there was a proctitis of gonorrheal origin in the case reported. Ten such cases had been reported in which gonorrhea of the rectum had been occasioned in this way, *i.e.*, through the recto-urethral fistula.

Dr. Ramon Guiteras said he admired Dr. Ware's courage in reporting such a case. He said he had gone into the rectum three times while doing perineal sections. In looking through the literature there were but few men who reported such accidents, and he began to think he was the only one who had committed such an act until conversations with his friends proved differently.

Dr. Martin W. Ware said he once had the misfortune to get into the rectum while doing a prostatectomy; the rent was sewn up, and the patient made a prompt recovery. He referred to another patient, an old gentleman of eighty years, who was doing very well after a prostatectomy, but, in giving an enema, the nozzle was pushed through the rectum. In reply to Dr. Spooner's question, I wish to state that the prostatic abscess revealed no gonococci, although the pus from the urethra did. The pus from the prostatic abscess showed pure cultures of staphylococci.

Instrument for Cocainizing the Deep Urethra.—Dr. L. Bolton Bangs presented this instrument, using in it a preparation called "neurococaine," made by Schieffelin, pure pellets of it being very soluble in the

natural moisture of the urethra. With this instrument Dr. Bangs could deposit the pellet at any spot in the urethra, and anesthetization of the part rapidly followed. The best time for operating was from five to six minutes after the pellet had been deposited. The major portion of the prostatic urethra could be thus anesthetized, but more than one pellet might be necessary. Each pellet contains 1-12 grain of pure cocaine.

Dr. J. Bentley Squier had had some practical experience with the instrument, and laid emphasis upon the necessity of keeping the pellet perfectly dry until deposited. Even before introducing it into the instrument it should be perfectly dried.

Apparatus for Suprapubic Drainage of the Bladder.—Dr. Ernesto S. L. Blascutti presented this apparatus.

New Method to Aid in the Detection of Stone in the Ureters and Kidneys.—Dr. Follen Cabot, Jr., said that although several methods for detecting stones in the ureters and kidneys were spoken of, it occurred to him that the sense of hearing could be utilized for this purpose. Accordingly, with the aid of the stethoscope first, and then later the phonendoscope, he had devised an instrument which he believed would be of considerable assistance. A whalebone bougie, thirty inches long and with a blunt end, was placed in the catheter and one end received into the diaphragm of a phonendoscope. The slightest sound of a stone could be detected accurately by this means. This was simply a preliminary report and the result of considerable experimental investigation.

Concerning the New Electro-Cystoscope.—Dr. William K. Otis said that the invention of the new electro-cystoscope has completely revolutionized our methods of diagnosis in vesical disorders, even extending to a determination of some of the lesions situated in the kidney itself, giving definite information regarding conditions which formerly could only be surmised, and may well be considered one of the great advances of modern surgery. The credit of this brilliant invention belongs entirely to Dr. Max Nitze, of Berlin. It differs entirely in principle, design and scope from any method for the ocular examination of the bladder which preceded it, and subsequent instruments have been modifications of this one. Over twenty-five years have passed since the first cystoscope was presented to the profession, and although the incandescent light has been added since its invention no one has succeeded in improving the ocular apparatus, and the cystoscopes of to-day are no better than those made in 1887. The electro-cystoscope presents many difficulties in the making; not only does the workmanship require the most experienced and skilled mechanic, but one who thoroughly understands the construction of electrical instruments and has a thorough knowledge of optics and the ability to construct and even originate a complicated ocular system. With the aid of a skilful electrician Dr. Otis had been able to present in 1899 the first electro-cystoscope manufactured in this country and until this time it was impossible to have one repaired without sending it abroad. One of the faults of the instrument was the difficulty of securing a larger field. After many experiments and many failures this obstacle was overcome by entirely eliminating the prism and substituting in its place a hemispherical lens, the plane surface of which was silvered, a portion of the circumference filling and closing the window in the outer tube of the instrument. This overcame the objections pertaining to the use of the prism as a means of diverting the rays, enlarging the field, and increasing its illumination. Dr. Otis then presented an instrument which resembles in general the cystoscope of Nitze, but differs from it in several important features. It consists of two separate parts, the external catheter, or sheath, carrying the illumination, and the internal, or telescope, in which the entire optical apparatus is contained. The lamp is of peculiar construction, of wonderful brilliancy and freedom from heat. One pole of the lamp is carried on the metal shaft itself, the other by a specially insulated wire, and permits of the use of a telescope several sizes of the French scale larger than that of other instruments, thus allowing the passage of a greater amount of light with a corresponding brilliancy of field. Dr. Otis described the difference in insulation compared with the Leiter instrument, and showed how the mechanism of his lamp was manipulated. He also described the ocular apparatus, and said that after the instrument is well in the bladder if the fluid in the bladder becomes cloudy on account of bleeding or the presence of pus it is only necessary to remove the telescope, the sheath acting as a large catheter permits the rapid withdrawal of the fluid contents of the bladder, which can be refilled, the telescope replaced and the examination continued without the loss of a great deal of time, and without removing the instrument. This is much more effective than the so-called irrigation cystoscopes. To describe this complicated instrument in detail was unnecessary, as it is the practical advantages that interest surgeons, and in this cystoscope these are: A field having an area four times as large as that of any other rectangular cystoscope, so that it is practically impossible to overlook a pathological condition in the bladder. The field is clearer and brighter on account of the more powerful illumination of its lamp, the greater caliber of the telescopic tube, and the arrangement of the lens system. The lamp has such a low amperage that it emits very little heat, making it quite impossible to scorch or, as has happened, to seriously burn the bladder wall. This cool, powerful lamp, together with the protection of the lens from being smeared during introduction, permits the use of air as the examining medium, whenever it is considered advisable. The short beak and the absence of the flat top and sharp angular sides of the prism render it easy of introduction and less liable to cause bleeding. Should the medium in the bladder become clouded it can be rapidly withdrawn and replaced without removing the instrument. The exquisite workmanship of the instrument will challenge comparison with foreign cystoscopes of the first class.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, held March 8, 1905.

General Blastomycosis.—Dr. Daniel N. Eisendrath exhibited a case of general blastomycosis. Beautiful examples of the organisms of the disease were obtained from the ulcer on the patient's leg by Dr. Ormsby. He said the disease was first brought to our attention some seven or eight years ago, since which time there have been quite a number of cases recognized and reported. The disease is characterized clinically generally by one lesion, but with more or less general infection. It is characterized locally by the fact that the edges of the lesion are raised, sharply demarkated from the surrounding normal skin. These contained a number of small miliary abscesses. Another characteristic of the surface was a peculiar wart-like or papillomatous condition of the ulcer. It was upon this, even without a microscopical examination, that the diagnosis of blastomycetic dermatitis was made, concurred in by eminent dermatologists, and the patient brought to the Cook County Hospital. The patient was a Bohemian, forty years of age,

and first noticed a small, circumscribed abscess which appeared upon the left side of the chest, which healed after the use of medicine, patient noticed an ulcer forming upon the place where the largest ulcer existed at the present time—the posterior surface of the right limb. This had gradually enlarged. Patient had an ulcer of the typical blastomycetic type on the left heel, two on the right leg, one of which was large. He had an abscess that formed spontaneously upon the anterior aspect of the right elbow; and some characteristic warty excrescences covered by some crusts under his chin. The author discussed the differential diagnois of this disease from tuberculosis verrucosa cutis, from carcinoma and syphilis.

Diffuse Septic Peritonitis Following Appendicitis.—Dr. Eisendrath presented three patients illustrating the progress surgeons were making in the treatment of diffuse septic peritonitis complicating appendicitis. These patients were operated on at a period ranging from twenty-four to seventy-two hours after the onset of the disease. In one of the cases perforation occurred into the free peritoneal cavity. In one there was no perforation of the appendix, but there was a virulent type of appendicitis which was generally recognized as streptococcic, with general invasion of the peritoneum. These patients could not have been saved, he said, five years ago with the methods then in vogue, and the profession had to thank one man for helping us to improve the percentage of recoveries in these cases—Fowler, of Brooklyn, who, in 1900, published a paper in which he recommended the Fowler position in operations for diffuse septic peritonitis, together with flushing freely with salt solution, inserting drains, and instead of letting the patients lie flat on their backs, propping them up in bed or elevating the head of the bed, the object being that pus would not gravitate toward the diaphragm where the large lymphatics were, and by inserting drains in the pelvis one could get rid of the pus more quickly than by any other method.

Hodgkin's Disease.—He showed a well-marked case of Hodgkin's disease, which he intended to subject to the X-ray treatment. Dr. Eisendrath also reported a case of skin-grafting by the Wolf method; a case of encapsulated tubercular peritonitis, and a case of non-development of the testes in a man, thirty years of age.

A Case of Aortic Insufficiency.—Dr. Rosalie M. Ladova read a paper with this title, in which she quoted a case. The patient, Mrs. W. S., American, aged fifty-two years, housewife, family history negative. Personal history: At the time of the Civil War the patient sought medical advice for attacks of dyspnea, and was then informed of a heart lesion. She had recurring attacks of dyspnea, but had no medical attendance until January, 1903, when the attacks increased in severity, and edema of the lower extremities reached above the knees. Recovery followed, and she was without medical supervision again until January 6, 1904, when Dr. Ladova saw her for the first time. She found her in a state of extreme dyspnea and cyanosis, with a pulseless wrist and subnormal temperature; restlessly tossing herself in a vain effort to get her breath, with a look of despair in her eyes. She was a picture of distress. For the stertorous respiration, the heart sounds were inaudible; the cardiac impulse could not be felt. Under stimulation and the use of the morphine she rallied and was much improved; the attacks recurred on the tenth and eleventh; she became unconscious and delirious; while her pulse responded to stimulation, her mental state remained the same, and she died in the evening of the eleventh. Contrary to instructions, patient was fed fermented preserved peaches and corn starch pudding, which undoubtedly precipitated the end. Pulsation in the carotid and thyroid arteries; throbbing in the superficial veins of the neck; cardiac impulse diffuse; pulse 76; not of the water-hammer variety; temperature 94.4° F.; respirations 26; apex in the sixth interspace in the nipple line; only a moderate degree of arteriosclerosis; heart dulness from the third rib to sixth interspace in the nipple line, one inch to the right of the sterum; lower border about two fingers' breadth below the costal arch. Moist mucous râles in posterior lobes; diastolic murmur at the aortic area, heard all over the precordia, transmitted down the right border of the sternum; round ulcer on the anterior surface of the thigh. Urine showed a trace of albumin, otherwise normal. Pathological diagnosis—post-mortem—showed insufficientia valvulæ aortæ, hypertrophia cordis; atheromatosis aortæ; emphysema pulmonum; œdema pulmonum; hydrothorax dextra; concretio pulmonis sinistræ cum pleuræ perietalis; hydro-pericardium; infarctus hemorrhagicus pulmonis dextræ; tuberculosis obsoleta apicis sinistræ; morbus Bright's chronicus; hyperemia mechanica hepatis et lienis; myomata uteri; pelvio-peritonitis obsoleta; hydrops ascites; gastritis chronica; epithelioma cruris dextræ; anasarca et marasmus universalis. The clinical interest in the case centers in the almost miraculous recovery, in view of the post-mortem findings, from an extremely severe attack of angina pectoris, and impending paralysis of the heart, and in the probable further improvement, frustrated by a dietic error. Other unusual features were diffuse transmission of the murmur within the precordia and its limited transmision outside of the same; pulse not intermittent and not of the water-hammer variety, quickly responding to simulation; impaired temperature sense. Etiology, outside of only a moderate arteriosclerosis, lacking. This lesion is rare in females. Of 53 cases collected by Babcock, there were only 7 in females; urine normal with a distinct renal lesion; extreme multiplicity of post-mortem findings.

Complete Perineal Prostatectomy by Young's Technic.—Dr. Jacob Frank read a paper on this subject, in which he reported two cases. The first case, Mr. C. B., aged seventy years, consulted him May 15, 1904, complaining of having been troubled with frequent and painful micturition for nine months, passing very little urine at the time, and after having had to resort to the use of the catheter several times at intervals during this period, he had been compelled to lead daily catheter life for the past five months, suffering agonizing pains, insomnia, anorexia, loss in weight, a great deal of residual urine, quantity in twenty-four hours, 58 ounces, specific gravity 1.023, with albumin present, no sugar, abundance of pus cells, and also some squamous cells. Reaction was acid; no blood; urea 2.1 per cent. in twenty-four-hour specimen. The albumin reaction was thought to be due to the presence of pus. The family and personal history otherwise negative. Patient has double inguinal hernia and lipoma in the right groin. He was sent to the German Hospital May 29, 1904; put to bed; kept on a strict liquid diet; urotropin, 5 grains, was administered every four hours; lithia water given in abundance; boric acid irrigation of the bladder daily at a temperature of 110° F., and the daily use of the prostatic catheter, as the soft rubber catheter could not be introduced. Normal salt solution twice daily per rectum, as the patient was emaciated and required careful preparation. The gland could easily be palpated through the abdomen, especially per rectum. The lateral lobes were greatly enlarged, as was also the median, and not very tender, not as hard and immovable as the one in the second case. The operation was

performed June 2, 1904, four days after admission to the hospital. Young's method was used, and chloroform anesthesia employed. The patient was put in the exaggerated lithotomy position; a grooved sound as a guide for urethrotomy was introduced into the urethra; an inverted-shaped incision was made, the apex of which was just over the posterior bulb, and the two arms, each about five centimeters long, midway between the anus and ischial tuberosities. After exposing the superficial muscles by blunt dissection, the central tendon was caught by a clamp near the bulb and divided; this freed the sphincter and levator ani from their anterior attachments, and exposed the rectum, drawn forward by the recto-urethralis muscle. This muscle was then divided and the membranous urethra brought into view. This latter step not only exposed the membranous urethra, but prevented injuring the rectum. After exposing the membranous urethra, the muscles were retracted and the apex of the prostate brought into view. The membranous urethra was opened on the previously introduced grooved sound, and the edges retracted with transfixed silk retractors. A No. 30 French sound was then introduced through the urethral incision into the prostatic urethra and bladder, and the sphincter dilated with an easy to and fro motion of the sound. The prostatic tractor, closed, was then carried into the bladder, while the edges of the urethral wound were held apart by the silk sutures. As soon as the beak of the tractor was free in the bladder, the thumbscrew, which fixes the blades in position, was loosened, the blades rotated 180° by means of the external blades, and fixed by tightening the thumbscrew. The instrument was then handed over to an assistant, who made enough traction on the instrument to bring the gland clearly into the field. Lateral retractors were now placed so that, together with posterior retractors and the traction produced by Young's tractor, the entire posterior surface of the gland was exposed. The capsule was now incised to a depth of 1 cm. on each side of the median line for almost the entire length of the posterior surface of the gland, the two lines being convergent, the widest part measuring 1.8 cm., the narrowest, 1.5 cm. The bridge of tissue contains the ejaculatory duct, and hence in some of Young's patients sexual potency was not impaired. By means of blunt dissection, and with the aid of Young's forceps, the right and median prostatic lobes were enucleated piecemeal. The left lobe was enucleated *in toto*, measuring 5 by 8 cm. The tractors were then withdrawn, and a double drainage tube introduced into the bladder through the opening in the membranous urethra, the inlet tube being about one-third the size of the outlet tube. This double tube was fastened with a suture to the upper angle of the perineal wound. The lateral cavities left by the enucleation prostatic lobes were packed with plain gauze, and the drainage tube connected with a siphonage arrangement, and continuous irrigation with normal salt solution, 110° to 120° F., thus kept up, the flow being regulated by means of a screw clamp in the inlet tube. The irrigation was commenced on the table to prevent blood clots forming within the bladder. On the second day after the operation the patient developed an orchitis on the left side, very likely due to the extreme force used by the assistant in making the traction. The swelling was successfully treated with ice-bags, and elevation of the scrotum. The rectal temperature for the first week ranged between 100° and 103° F.; pulse between 78 and 98. The temperature was due very likely to orchitis, and also to the temperature of the irrigation fluid flowing so near the rectum. No shock. Pain for the first few days was relieved with one-quarter of a grain of morphine administered hypodermically. Two hypodermic injections in all were used. On the second day the gauze packing was loosened, and some of it withdrawn every day until the sixth day, when all of the original packing was removed, and the superficial wound kept open thereafter with a small gauze pack. The patient was allowed to sit up in bed with a backrest on the fourth day. At the end of the week the continuous irrigation was stopped, and the drainage tube withdrawn. On the ninth day a No. 28 French sound was introduced through the urethra into the bladder, when a soft rubber catheter was carried into the bladder through the meatus, fastened, and the bladder irrigated twice daily with boric solution through this catheter. Five days later the catheter was withdrawn, no urine yet coming through the meatus, as the perineal opening was too large. On the nineteenth day the patient voided some urine through the meatus, but most through the perineal opening. From this day on the patient pased more urine daily through the natural channel, and at the end of the fourth week most of the urine pased through the natural opening at intervals of every two hours. With a 30 or 31 French sound his urethra was sounded every other day, and irrigated once every day after the second week. In five weeks after the operation the patient left the hospital with a very minute perineal fistula, which was dresed daily. At the end of the sixth week all was healed, patient urinating every three to four hours. The urine was quite clear, and there is no residual urine. He enjoys very good health, eats and sleeps well, and has gained considerably in weight. He was impotent before the operation, and is so now. Dr. Frank narrated another case in a man of sixty-two years, in which the result following Young's method was very satisfactory.

Chloride Retention in Nephritis.—At a recent meeting of this Society, Dr. Joseph L. Miller read a paper in which he said that a review of the literature since Widal and Javal's original communication showed quite uniform confirmation of their views, that patients with acute and chronic parenchymatous nephritis have marked inability to eliminate chlorides. As a result of the retention, the patient increases in weight, due to edema. The albumin in the urine, following the ingestion of ten grams of sodium chloride daily is increased and the patient may develop symptoms resembling uremia. In animals with artificial nephritis the use of salt increases the albumin. The organs of patients with nephritis show excessive sodium chloride. Kovesi has shown that nephritics after the ingestion of large amounts of NaCl do not perspire, due to increased osmotic pressure of the blood, and the edema is the result of this retained fluid. As it has been shown that ingestion of large amounts of salt may increase the edema, due to portal obstruction, cardiac insufficiency, and even the inflammatory edema, many believe the chloride retention is of extrarenal origin. The author has studied two cases of acute and seven of chronic parenchymatous nephritis. The chlorides were estimated by the Salkowski-Volhard method for nine consecutive days. For three days in the middle of this period the patients received in addition to their food ten grams of sodium chloride daily. All showed a retention of ten to twenty-five grams during the three days. The edema became more marked, the patients gained in weight, and the amount of albumin increased. Two patients showed uremic symptoms following the extra sodium chloride. Four normal individuals were examined in the same manner, and all showed a chloride retention equal to the nephritis. They also gained in weight. From this it is concluded that

these patients developed an undetectable edema, while in the nephritics, with the tissues already waterlogged, a moderate increase in edema could be detected. These patients did not show any albuminuria or uremic symptoms. As a final conclusion, in this matter, there is no doubt that the sodium chloride should be restricted in nephritis. The broths and soups contain very large amounts of salt. That furnished the patients in Cook County Hospital contains 11.3 grams per liter. Subcutaneous injections of salt solution must be used with caution, if at all.

Present Limitations in Serum-therapy.—Dr. H. T. Ricketts read a paper on this subject, and said that inquiry into the value of diphtheria antitoxin and of tetanus antitoxin revealed the fact that the latter fell far below the former as to its therapeutic value. The antitoxin treatment of tetanus might be considered hopeless, at present. However, observations and investigations showed that there might be a brighter future for it; but subcutaneous injections of tetanus antitoxin had given poor results. Intracerebral injections of the antitoxin of tetanus reported by Roux had not been given a sufficient trial for one to judge of the actual therapeutic merits. The chief value of tetanus antitoxin was its prophylactic use, as it had been clearly demonstrated that if the antitoxin of tetanus was given to a patient in whom there was any suspicion or likelihood of the development of tetanus, the disease did not develop. A striking example of this was seen in Fourth-of-July wounds. In some of the Eastern hospitals, patients who had received wounds on the Fourth of July, and had been injected with tetanus antitoxin as a prophylactic, did not develop the disease. In a hospital in Prague, a threatened epidemic of tetanus was controlled by giving prophylactic injections of tetanus antitoxin to all inmates in the institution. The therapeutic value of diphtheria antitoxin was so well established and known that little or nothing need be said regarding it.

Bactericidal Sera.—In regard to bactericidal serums, practically no results of value had been obtained in the treatment of established infections by antityphoid serum, anticholera serum, or antiplague serum. Published statistics did not warrant the conclusion that so-called bactericidal serums were of any value in treating diseases. Antistreptococcic and pneumococcic serum were of very little value.

Plague and Late Cholera Epidemic in the Philippine Islands.—Dr. Paul C. Freer, Superintendent of Laboratories of the Philippine Islands, stated that the Philippine Islands had been visited by two cholera epidemics before American occupation, one in 1882, and the other in 1888, and in these years the mortality was very high. In Manila alone the records showed that there were as many as a thousand cases at one time, and proportionately a number in progress. Both of these epidemics were serious, and so far as could be discovered very little was done to check them. During both of these epidemics Manila had no water supply except from wells, and it was after the second epidemic of 1888 that one of the former Governor-Generals gave a donation to start the Manila water supply works, which was completed afterward. The third cholera epidemic occurred during the American occupation, and about three years after Americans landed on the Islands. Before speaking of the measures which were taken to limit the spread of the disease, Dr. Freer referred to the organizations in the Philippine Islands and the scant means at hand for limiting the epidemic. He also mentioned those who took an active part in stamping out this epidemic. In order to secure complete cooperation, the Philippine Commission established a Board of Health. This was composed of a Commissioner of Public Health, a Secretary, who was a Filipino, a Chief Health Inspector, and a Sanitary Engineer, who took charge of the engineering department, and a Superintendent of Laboratories. When the Board of Health was organized in 1901, it found itself practically without means. It had plenty of financial means, but it was without ambulances; it had no contagious disease hospital; it had no disinfecting wagons, and, in short, organization was very incomplete. Means of transportation were very poor, although these in times of epidemics were very important. The Board of Health undertook the work of equipping itself and preparing for future work. The City of Manila was divided into seven districts, each in charge of a medical officer, who were taken from the contract medical service. These officers, together with a corps of medical inspectors, began a system of house to house inspection. At this time the most serious disease confronting them was bubonic plague. They were having a number of cases a day, although the number had diminished markedly since American occupation. Still it was serious, and a recrudescence of the epidemic was feared, and for this reason the energies of the Board of Health were devoted toward diminishing the plague epidemic. Many of the facilites acquired for controlling the plague epidemic were put to good use subsequently in dealing with cholera. Three weeks after the organization, a large barracks was constructed which would hold twenty-five hundred people. This was for the sole purpose of isolating plague patients.

When plague occurred in a house, the patients were taken from it to the hospital, thus leaving the premises free for disinfection, etc. About December, 1901, three months after the plan was first discussed, there were constructed six barracks, which would accommodate a thousand people comfortably, and during the cholera epidemic they took in as many as twenty-four hundred at one time. The Board of Health procured eight or nine ambulances and equipped itself as well as it could with disinfecting apparatus, etc. Whenever plague was suspected to exist in a certain house, a member of the laboratory staff was called in for diagnosis, and if the case proved to be plague, the patient was taken to the hospital, or, if he died, to the morgue, and a radical alteration of the house undertaken, either its destruction by fire, if beyond repair, or complete rebuilding. It became necessary to destroy and rebuild whole districts in the city, altering the houses, putting in new floors and walls, new windows, and in this way plague was eradicated completely from the districts where it was prevalent. The main weapon against plague was the destruction of rats. The Board of Health undertook this work and in the first month destroyed about two thousand rats, after which the number ran up to as much as twenty thousand a month. Fifty thousand rats were caught in the first three months. A very large number of rats were examined at the laboratory for the plague bacillus. Two hundred and seventy-two rats were found to be infected with plague and had come from various houses, and one-half of the houses infected with these rats were found and treated in exactly the same way as those houses in which there were human beings infected with the disease. These houses were disinfected, even burnt down, if necessary, or altered. They managed to diminish the number of cases of plague by these measures, so that in March, 1902, there was not a case of plague in the city, nor had there been one for three weeks.

Epidemic of Cholera.—With reference to the epidemic of cholera, the Board of Health, before the confirmation of the diagnosis by culture in the first two cases of cholera, had taken measures as if they were

cholera. The patients were isolated in a contagious disease hospital, poor as it was. The next morning there were five more cases, the following day twenty more, and before the end of the month there were over a hundred and sixty, with two or three cases coming from one particular district in the city. The houses in districts in which cholera was most prevalent were burnt first and the property appraised afterward, as it was found that it would take at east two weeks to appraise the property. Two thousand people were taken out of the infected district and transported in wagons, ambulances, etc. By carrying out these measures there was very soon a great diminution in the number of cases until finally the disease was entirely controlled and eventually wiped out.

Prophylactic Sera.—The question of prophylaxis and of the use of sera having become a serious one, a serum laboratory had been established, and under the Bureau of Laboratories, where formerly everything was imported from Japan, this laboratory now made all of the antitoxins and sera necessary for work in the tropics, including rinderpest serum, which was the largest item of all. The Board of Health had procured new ambulances, had enlarged its disinfecting corps, and had perfected district organization.

Tricuspid Obstruction; Report of a Case Associated with Mitral and Aortic Lesions.—Dr. Joseph M. Patton, in a paper on this subject, spoke of the frequency, etiology, morbid anatomy, symptoms and diagnosis, and prognosis of this condition, and cited an interesting case which was under the care of Dr. C. B. King, who furnished the history: Patient, M. H., aged twenty-four years; father died when she was two years of age. Mother died at patient's birth. No brothers or sisters. Married at the age of fifteen years; never pregnant. First saw patient in spring of 1900. At that time she was suffering from incompetency, exhibiting some edema of feet and limbs; lips and fingers purple, shortness of breath, and pain in precordial region radiating into both arms. The heart was greatly enlarged; apex seventh interspace, three inches outside nipple line; right ventricle one inch to right of sternum. There was a double murmur at both aortic and mitral openings. The first aortic sound was so loud and rough that it covered the whole of the front of the chest. She responded quickly to strychnine and digitalis; the edema of feet and limbs disappeared, and during the following summer she got along very well, doing some housework. The following November she again suffered from lack of compensation; edema of feet, limbs and lungs, and severe pain radiating to the fingers of both hands. Ventricles dilated, left reaching to midaxillary line; unable to lie down, eat or sleep; urine very scant and loaded with albumin and casts. Ordinary dosage of strychnine and digitalis produced no reaction; dosage increased at this time to digitalis, 17 drops, every two hours; strychnine, grains $^1/_{30}$, every two hours, for three days. At this time Dr. J. M. Patton saw her in consultation. Digitalis had produced nausea by this time, and a change was made to digitaline (Merck's German pure), grains $^1/_{16}$, every three hours, was given. In a few days there was a gradual response. Kidneys gradually improved, heart became competent, digitalis and strychnine reduced to $^1/_{30}$ of a grain of each three times daily. The following March she was able to leave the house and appeared at Dr. Patton's clinic. Since then, during the warm weather, she got along very well unless she became negligent with the strychnine and digitalis. At times she would go several weeks without medicine. During cold weather she had more trouble. In September, 1903, she spent the month in the woods of Wisconsin, and seemed to improve a great deal. During the winter of 1903 and 1904, she had two or three slight attacks of incompetency, but responded quickly to full dosage of strychnine and digitalis. In June of 1904 she suffered a severe attack of incompetency, and entered St. Luke's Hospital, was there for about six weeks, and from there she went to Grove House, Evanston, and remained there until about the middle of December, 1904. While there she had no medicine, except the supply that was given her on leaving St. Luke's, and which was soon exhausted. He saw her again on December 23, when she was suffering from all the symptoms of incompetency. At this time she did not respond to the large doses of strychnine and digitalis. December 27, she entered Mary Thompson Hospital, and died there December 29. Although the patient had recognized her physical limitations from childhood, she gave no definite history of rheumatism. He first saw the patient in November, 1900. Inspection showed forcible, heaving heart impulse, which moved the whole of the anterolateral portion of the left side of the chest wall. There was some systolic pulsation at the second and third interspaces at the left of the sternum. The cyanosis was very slight. Dyspnea was marked.

Palpation determined the apex impulse to be approximately in the seventh interspace in the anterior axillary line, the impulse being so diffuse that accuracy in location was impossible. The character of the impulse was distinctive of extensive dilatation of the left ventricle. A mitral presystolic thrill was felt midway between the mammillary and anterior axillary lines. It did not extend to the right of the mammillary line. A systolic thrill was felt at the area of pulsation before mentioned. There was no thrill along the left edge of the sternum Jugular and hepatic pulsation were absent. Percussion determined the lateral limits of cardiac dulness at the level of the fourth rib to be one and one-half inches to the left of the mammillary line on the left, and one-half inch to the right of the right sternal border on the right. Auscultation determined double aortic and mitral murmurs. The aortic systolic murmur was unusually loud and rough, and was transmitted over almost the entire front of the chest, being particularly pronounced from the second to the fifth ribs along the right parasternal line. The other murmurs had the usual characteristics, their points of greatest intensity being modified in accordance with the change in position of the heart. The diagnosis was in accordance with these findings, moderate dilatation of the right auricle and slight tricuspid regurgitation being recognized. The possibility of a tricuspid lesion was considered, but nothing definite was recognized. The autopsy, at which Dr. Patton was present, was made by Dr. King fourteen hours after death. There was considerable fluid in the pleural cavities, and a moderate quantity in the pericardial sac. No evidence of pericarditis. The heart weighed twenty-four ounces (normal for women, ten to twelve ounces). It showed extensive hypertrophic dilatation of the left ventricle, moderate of the right ventricle, marked dilatation of the left auricle, and considerable dilatation of the right auricle. The aortic opening is irregularly oval in shape, and measured 1½ by .5 cm. (average for women .9 inch). The upper surface of the ring presents an irregular, hard, rough ridge, without evidence of valvular structures. The inner surface is sharp and rough, while the lower is rough, irregular, and presents near the edge of the opening a calcareous vegetation a quarter of an inch long by about one-eighth in height. The whole ring is calcareous and of almost bony hardness. The mitral opening is oval in shape, and measured 2 cm. by ½ cm. (normal for women, 1.2 inch). The upper surface of the ring is hard and smooth, the inner surface rough. The valves are thickened, rigid,

with rough thick edges which form an almost continuous ring. The tricuspid opening is almost round and measured 1½ by .7 cm. (normal for women, 1.5 inch). The upper and inner surfaces of the ring are rough, irregular and hard. The valves are thick, retracted, and partly adherent at their bases. The cavity of the left ventricle measures five inches, from base of valve cusp to apex of cavity (average for women .3 inch). The wall measures over one inch in thickness near the base of the ventricle (normal, one-half inch), and one-half inch at thinnest part of apex (normal, one-quarter inch). The left auricle is much dilated and its walls are one-eighth inch thick. The cavity of the right ventricle measures 3½ inches (normal for women, $3^{3}/_{16}$ inches); its wall is one-half inch thick. The right auricle is somewhat dilated and its wall is one-twelfth inch thick. The physical changes in the heart in this case explain and are in accord with the clinical symptoms, which were those of aortic and mitral disease, and not at all indicative of tricuspid lesion. The absence of any hypertrophy of the right auricle shows that the tricuspid lesion had no such effect on the auricle as had the mitral lesion on the left auricle. While the tricuspid lesion is of considerable pathological interest, it has little bearing on either the clinical history and symptoms or on the physical changes in the heart. In these respects the case corroborates the majority of cases previously recorded, and illustrates the fact that tricuspid lesions have, as a rule, less clinical importance than other valvular lesions, and especially than those with which they are associated.

KENSINGTON BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held March 7, 1905.

The Chairman, Jas. C. Chestnut, M.D., in the Chair.

The Treatment of Retroflexion of the Uterus. Based on Records of 653 Cases.—Dr. Barton Cooke Hirst read this paper, and stated that out of over 6,000 cases of diseases of women that had come under his observation in private practice, and at the Howard and University Hospitals, he had done over 1,400 plastic operations and 653 cases were treated for retroversion of the uterus, 506 of which were subjected to operation. He stated that the physician should consider three questions before advising operation or operating: (1) Is operative treatment satisfactory? (2) Is the physician justified in operating? (3) What form of operation should be used, in relation to each individual case? He believed, in young married women and in working-women, operation should be advised if there was no contra-indication, but in a case of adherent retroversion with exophthalmic goiter pessary treatment would be preferable. He also stated that some cases may be cured by the pessary, and in many cases it is necessary to use it for a time at least. He stated that the best method of procedure was the modified Alexander operation, as it presented the least proportion of recurrences and least difficulty in subsequent pregnancies, but can be used only in uncomplicated cases. The suspension method, he stated was the most generally available, the percentage of failures was small, and in the cases examined there were only three recurrences and in only one of these was there any congestion of a serious character. The vaginal fixation operation, he stated, had the highest percentage of failures and was the most difficult. The Jacksonian procedure of utilizing the coronary ligament he considered worthy of consideration. The cases of acute displacement following a sudden jolt, he recommended be treated without support. He cited two cases, one of a young woman who fell down a flight of stairs resulting in complete backward displacement of the uterus and another in whom the displacement was caused by a fall over a tub; in the former the uterus was in good position six months after replacement, and in the latter four years. The third case was that of a married woman who on examination after childbirth was found to have complete retroversion of the uterus. No supports except dry tampons were employed, and she was examined nine months later and found to have complete retroversion of the uterus. He recommended that during the puerperal period the patient be examined at the beginning of the fourth week, and if the uterus is out of place, it should be replaced, if necessary, by putting the patient in the knee chest posture, and pessary and tampons should be introduced, if necessary, after six weeks, and the treatment should be accentuated by Swedish movement and massage. Three cases, each of which had retroversion following several deliveries and were cured by the treatment outlined were cited. He referred to four cases in which the retroversion had been cured by subsequent pregnancy. Operation should not be done immediately following childbirth. He stated that he believed hard rubber was the best material usually available for pessary; aluminum he believed to be a good, exceedingly light and does not corrode, but difficult to obtain, and the pessary should be only just large enough to retain the uterus in position. The pessary should be removed once in eight weeks and cleansed by the physician, and vaginal douche of boric acid solution should be taken on the two days following menstruation and once between the periods. He referred to a case which he examined, in which the symptoms pointed to cancer; after removing a pessary the symptoms disappeared.

Ventrosuspension Operation.—Dr. Frank C. Hammond stated that while there were many operations for this condition, there was none that could be called an ideal one. He stated that he was glad to see that the author used the ventrosuspension operation. The operation of shortening the round ligament, he stated, did not give good results, and the Alexander operation he did not look upon as satisfactory, as it requires two incisions, which, if nothing else would increase correspondingly, the likelihood of subsequent hernia and also the likelihood of complications in subsequent pregnancies. He referred to a case which had come under his observation at the Samaritan Hospital in which a woman, forty-three years of age, in whom a fixation had been done two years before by an operator outside of Philadelphia, followed by adhesions which finally required another operation. He referred to another case which he had examined in which the woman had worn a pessary for two years for backward displacement of the uterus, and when he examined her it was found to be upside down, the woman reporting that she had repeatedly taken it out and washed it and reinserted it herself. He believed the pessary would give good results in selected cases, but before it is employed, we should ascertain (1) whether the uterus is pregnant and (2) we should make sure that it is free from lacerations and inflammatory disease. He referred to a case in which a physician had diagnosed anteflexion and introduced a pessary, which the patient could not wear, and she went to another physician who diagnosed backward displacement and also introduced a pessary. The patient then came under the speaker's care, and examination under ether revealed a fibroid in each anterior wall. He also referred to the uselessness of the employment of the pessary in cases of rectocele and

cystocele, without correction of the condition. He also called attention to the fact that in a certain percentage of cases of headache and backache, which were otherwise unexplained, backward displacement of the uterus was the cause.

Dr. Chas. L. Leonard referred to a case which was diagnosed as pelvic disease, in which examination under the X-ray revealed an imbedded pessary.

Dr. Shaller referred to a case in which a ventrosuspension had been performed three years ago at a hospital and proved to be a marked failure, because of the fact that the patient was at that time suffering from a tear of the perineum and cystocele and rectocele, and emphasized the importance of attention to such conditions.

Obscure Fractures Diagnosed by the X-rays.—That paper was read by Dr. M. K. Kassabian, who, after referring to the progress made in the various lines of medicine, stated that he considered that the Roentgen rays were the most important discovery of recent years from a diagnostic and therapeutic standpoint. He referred to the fact that subjective and clinical symptoms were not always present, in which cases the X-rays were particularly valuable as a diagnostic agent. The advantage of this method of diagnosis were cited as: (1) It is painless. (2) There is no necessity to wait for the diminution of swelling or for the removal of the bandages. (3) In addition to the positive diagnosis, it is possible to reveal the exact nature, position, shape and size of the fracture, and to differentiate between the fractures and displacements. Among the conditions in which it can be used with particular advantage were named fractures, epiphyseal conditions, displacements of the bones, tendons and joints, ostitis and periostitis, tumors of the bone, diseased joints, etc. He then exhibited a large number of lantern slides showing the practical application of the methods outlined in the paper, including fractures of the bones in all parts of the body, diseases of the joints, periosteum, etc.

Dr. Chas. L. Leonard felt that Dr. Kassabian had failed to sufficiently emphasize the importance of the X-ray in making a negative diagnosis of fractures, thereby avoiding the necessity of keeping the limb in splints for a considerable period, in addition to being able to immediately apply the proper treatment for the consideration. He referred to a case which had come under his observation, suffering with pain in the lumbar and cervical spine, and who had been walking with a crutch and cane, who was said to have had a fracture of the tibia and possibly injury of the hip sixteen years previously. Examination under the X-ray revealed no injury to the hip, nor was there any fracture of the tibia, but there was about half an inch of shortening of one leg. Examination of the shoes he was wearing showed that in one pair he had a correction of an inch and a half, and in the other pair an inch and a quarter, which overcorrection had produced curvature of the spine. The correction in the shoes was reduced to the proper amount, the man was sent to Atlantic City for a couple of weeks, at the end of which time he returned to the city with absolutely no pain, and a week later went to his home with no pain and the only correction was a half inch in that shoe. In regard to the accuracy of diagnosis, he laid especial emphasis that it was possible to tell whether or not a joint was involved, and also what was necesary to be done in order to preserve the functional power of the joint, and also emphasized the value of the X-ray in medicolegal work, and exhibited a number of slides illustrating the various points of his discussion.

Dr. Franklin Brady emphasized the value of the X-ray in the differential diagnosis of intracapsular fracture, and referred to a case where a man had been kept in bed three weeks with his leg elevated in a plaster-of-Paris cast, supposedly for a fracture, when examination by the X-ray at the end of that time revealed that no fracture existed.

Dr. Kassabian, in closing, referred to the fact that the diagnosis of hip-joint condition, was difficult on account of the thickness of the parts, and stated that he always tied the feet together and took a skiagraph of both hips at once, so that if there was any deformity due to fracture it would show.

BOOK REVIEWS.

Medical Diagnosis, a Manual for Students and Practitioners. By Austin W. Hollis, M.D., Attending Physician to St. Luke's Hospital, New York, and to the New York Dispensary; Physician-in-Chief to the St. Luke's Hospital Out-Patient Department. Series edited by Victor Cox Pedersen, A.M., M.D., of New York. Illustrated with 13 engravings. Lea Brothers & Company, Philadelphia and New York.

Condensation is from the medical student's point of view, much to be desired; but the task of compressing the whole practice of medicine, including nervous diseases, into "epitome" size might properly be placed among the superhuman efforts. For the best of authors must fail to do himself or the subject justice, when he is compelled to limit himself to a series of headings with a few brief paragraphs following each.

Still, as a pocket-book to serve for rapid review, after the subject has been studied out of a "proper" text-book, we know of none better than this volume; for, in spite of the obvious difficulties of the task, the work is extremely well done. The sections on diseases of the chest, infectious diseases and nervous diseases are perhaps the most comprehensive. The book is printed on thin paper and can be easily carried in the pocket.

Essentials of the Practice of Medicine. By William R. Williams, A.M., M.D., formerly instructor in Medicine and Lecturer in Hygiene, Cornell University Medical College; Tutor in Therapeutics, Columbia University (College of Physicians and Surgeons), New York. Double Number. W. B. Saunders & Company, Philadelphia, New York and London.

Such an extensive use of these Question-Compends means that they in some way meet a want; and there is no doubt that when well-written they are commendable *aide-memoires* or "ready reviews" for the hard-worked student.

The great difficulty of the author of such a brief work is to cover any subject at all; for space limits him to the merest dogmatic statement, without modification or suggestion of other possibilities. This author has wisely followed the classification of the standard text-books, and has devoted himself to making an abstract of each article therein contained. He has not gone afield for new things, or the methods of the specialist, but has given us a concise and simple résumé of those things which are standards in Physical Diagnosis, Nervous Diseases and General Medicine. The brevity is most noticeable under the head of Treatment, where often a single line or perhaps two is all the direction one gets, as in Arthritis Deformans, Mumps or Bell's Palsy. The symptoms, however, are particularly well abstracted, and give the book real value.

ORIGINAL ARTICLES.

CLINICAL FEATURES OF THE BENIGN STENOSES OF THE PYLORUS.[1]

BY HENRY L. ELSNER, M.D.,

OF SYRACUSE, N. Y.

THE consideration of the Clinical Features of the Benign Stenoses of the Pylorus with their medical treatment, the subject which your presiding officer has invited me to consider in this symposium, would indeed seem to be hackneyed and threadbare were it not for its growing importance from a therapeutic standpoint. It may be said that we are passing through a transition period so far as the treatment of these conditions is concerned. Interesting experiences with individual cases, often unique, with the association of surprising pathologic finds which have finally cleared the horizon, still further justify the discussion which you have arranged for this meeting. The writer, in accepting your invitation, assures you that he fully appreciates the included privilege and honor. He will consider in his treatment of the subject those abnormalities, benign in character, within or without the stomach, which block its outlet sufficiently to interfere in any degree with the emptying of that organ or otherwise disturb its functions.

The benign stenoses of the stomach may be either (1) *functional*, or (2) *organic*. The latter may be either (*a*) congenital, (*b*) acquired. The acquired stenoses may be either intrapyloric or extrapyloric.

1. The *functional stenoses* are likely to be transitory, the patients highly neurotic. We have occasionally assumed the presence of *pyloric spasm* in cases where gastrectasia had persisted for months without producing symptoms, in which there followed periods during which the stomach became intolerant; there was peristaltic unrest with hyperacidity. In some the symptoms were aggravated by mental distress or other causes, including mainly those which ungeared the nervous system. Neurasthenia was always in the ascendency. In none of these cases did the evidences of stenosis become permanent, in none was there reason to suspect grave pathologic conditions.

There are also cases of *intermittent hyperchlorhydria without ulcer*, in which we assume the presence of pyloric spasm recurring at intervals of several weeks or months. There are severe pains, intolerant stomach, nausea, vomiting of large quantities of hyperacid fluid, severe headaches and often cerebral symptoms. With the epigastric pain, which may become severe, there is eructation of gas, visible peristalsis, constipation, a great thirst, complete anorexia. The total acidity is abnormally high so long as the symptoms persist, due to the presence of HCl. Young adults are most likely to develop these symptoms, and errors of diet, excessive use of sweets and mental emotion are leading factors. The chemical examination of the stomach contents differentiates these cases of probable spasm of the pylorus from ordinary migraine and gastric catarrh.

Occasionally we find a case of *acute dilatation* of the stomach with alarming symptoms, collapse without previous history of stenosis or other stomach disorder sufficient to direct attention to that organ. Some writers have reported deaths during such acute dilatation. Whether these cases are to be classified under pyloric spasm, as was suggested by Pepper and Stengel, has never been definitely decided. Robson and Moynihan speak of neuroparesis in connection with such serious, suddenly arising conditions. A few of these cases are recorded, promptly following operations in which it may be assumed that adhesions or other complications were more likely to have been the pathogenic factors than spasm or so-called neuroparesis. Two cases of acute dilatation seen by the writer seemed, in spite of the fact that there was no proof to justify the strong suspicion, due to overpowering toxemia. The true pathology of these serious and sometimes fatal cases can be decided only by the anatomic study of the individual case, when in all probability we shall find more than functional disorder.

Pyloric spasm may safely be considered secondary in the majority of cases and its presence must always lead to a strong suspicion of associated organic disease. On several occasions patients beyond middle life have been seen in consultation with symptoms of such spasm recurring at varying intervals, at times there was normal but gradually reducing HCl. production; in other cases the free HCl. was slightly reduced; in all of these lactic acid was absent. The end proved that we were dealing, at the time of the supposed spasm, with incipient malignancy. The urgent need of repeated chemical tests and physical examination at short intervals without undue haste to reach conclusions, must be emphasized in these cases.

The question has often arisen in my mind whether pyloric spasm is not occasionally present in neurotic girls, particularly during the menstrual period, with intolerant stomachs, marked and painful cramping of the organ, visible and persistent peristalsis. It is only exceptional that these hysterical girls have failed to vomit. The pain with peristalsis has persisted,

[1] Read before the American Gastro-Enterological Association, in New York, April 24 and 25, 1905.

yielding finally, not to alkalies but to appreciable doses of belladonna. The associated dilatation of the stomach has not persisted beyond the acute period.

It will be wise to hesitate long before diagnosticating a primary pyloric spasm in the adult, for it will be necessary to exclude organic disease by a thorough consideration of the separate functions of the stomach and the final elimination of mechanical organic obstruction at the pylorus.

Let us leave this part of our subject with the positive assurance that as we become more scientific we are the more thoroughly convinced of the rarity of functional disease and that, in considering the clinical features of pyloric stenosis, supposed to be dependent upon transitory nervous influences, we assume a mental attitude in which there is a fixed determination to accept such diagnosis, only after the greatest possible justified resistance.

2. *Organic Stenosis.*—A. *Congenital stenosis* of the pylorus may be of moderate degree, in which patients live for years with more or less continuous symptoms, a second class of cases in which the symptoms during the first year or two of life are sufficient to justify a suspicion of marked pyloric stenosis, in which, however, nature comes to the rescue, occasionally supplying such infants with almost normal functionating stomachs during life, and finally that serious class of cases in which symptoms are likely to follow birth, as a rule before the fourteenth day of life, never postponed beyond the ninth week (and this only rarely) in which death follows before the fourth month unless these infants are relieved by surgical interference.

It is not within my province at this time to consider the theories of the production of these stenoses known as spastogenic and hypertrophic, nor the Freund hypothesis which practically includes both spasm and hypertrophy as the cause of these. The writer recalls cases of congenital stenosis of moderate degree, in which all symptoms justified the diagnosis, which have yielded to proper treatment. Compensatory hypertrophy sufficient to overcome moderate mechanical obstruction must have followed. These cases include the child of a colleague in my own city with symptoms beginning at birth in which the child during the first two years of his life presented all of the symptoms of congenital stenosis, in which the boy, to-day twelve years old, is to all appearances perfectly well. In speaking to the father of the child while writing this paper, I was reminded of the fact that when the boy was one year old he weighed less than he did at birth, that his stomach was at that time still monstrously dilated, holding stagnant food, and that there was persistent peristaltic unrest.

The symptoms in all cases of congenital stenosis must follow birth immediately or cannot be long postponed. In four cases seen by the writer, three confirmed by post mortem, vomiting and other symptoms of indigestion first showed themselves, in the first before the end of the second day, in the second and third during the second week and in the fourth during the fourth week. In all of these cases there was marked visible peristalsis. It was by no means easy to detect the abnormally resistant pylorus; in all, the stomachs were greatly dilated, constipation and vomiting were constantly present.

Persistent vomiting in children, beginning after the ninth or tenth week of life, is not due to congenital narrowing of the pylorus. The majority of children with the congenital defect die before the end of the third or fourth month. Persistent vomiting in babes which begins shortly after birth is not as a rule to be interpreted as dependent upon congenital stenosis. Such conclusions would lead to great harm. Forcible projectile vomiting is quite characteristic of stenosis. The food seems to be held, only that it may be thrown far from the mouth and this suddenly, as a rule without warning. This is as true of breast-fed children as of those artificially and properly nourished. *No possible modification of the food relieves the symptoms where the stenosis is of high degree.* Single feedings may be held for a time and vomited with a second or third nursing. Couple these characteristics with marked visible peristalsis, even without palpable thickening, occasionally a high-pitched percussion note corresponding with the location of the pylorus, the physical signs of stomach dilatation, and the diagnosis becomes reasonably certain. Rapid wasting with many of the other symptoms found in the adult, as a rule ends the scene. *Congenital incomplete stenoses of the pylorus are frequently the cause of chronic disturbances,* as already mentioned, *which continue throughout life,* including marked and persistent gastrectasia, motor insufficiency, anomalies of secretion, symptoms of Leube's "nervous dyspepsia," including marked neurasthenia. These cases present a continuous train of symptoms with periods of marked exacerbation. While writing this paper such a case was sent to me in which a man forty-three years of age had never been without symptoms of stenosis and gastrectasia. The stomach is never free from stagnant food. His attendants have never failed to speak of his monstrous and persistent dilatation of the stomach, the palpable pylorus has been a surprise to all. This case is associated with hypersecretion and hyperacidity, peristaltic unrest, an enormously dilated, horseshoe shaped stomach. There is no history of ulcer. In spite of the relief of subjective symptoms by well-regulated treatment, the physical signs persist. Final gastric fibrosis, as described by Hanot and other French and German observers or the hypertrophic pylorus of Cruveilhier and Andral are sequelæ which materially influence the size and position of the organ as well as its functions in cases with almost parallel histories.

B. *Acquired Stenosis.—Intra-pyloric.* (1)

Cicatricial stenosis (chronic). The majority of benign stenoses are unquestionably due to ulcerative processes invading the pylorus. It is not always easy to get a clear history of preceding ulcer. That occasionally ulcers have existed without giving rise to symptoms there can be no doubt. As a rule, however, the previous history is direct, and close questioning with a thorough consideration of all that the case presents, proves the likelihood of previous destructive disease which justifies the reference of stenotic symptoms to consecutive cicatricial changes. If all cases of ulcer were associated with hemorrhage, chronic cicatricial stenosis due to this condition might be readily explained, for there is no symptom which the average patient remembers longer than hemorrhage, particularly when such alarming symptom is associated with severe pain. In these cases we are not limited to subjective symptoms alone or to the consideration of the previous history which may be vague and misleading. The physical examination of the patient, the absence of a large mass, the presence of dilatation, the revelations made positive by the stomach tube and an examination of the stomach contents, will be likely to clear the diagnosis. In those cases of chronic cicatricial stenoses which follow corrosive poisoning, localized phlegmonous inflammations and other chronic destructive changes, the previous history with a consideration of the clinical features and the absence of a large palpable mass will aid materially in confirming the diagnosis.

The writer feels justified in making the positive statement that in rare cases (and he has met with two of these in practice), there may be cicatricial stenosis of the pylorus following ulcer which has not undergone cancerous degeneration in which cancer nodules have been present in other organs of the body. The last case of this kind which came to his notice was that of a woman who had carcinoma of the uterus and liver with a benign cicatricial stricture of the pylorus. The persistent dilatation and evidences of benign stenosis covered a period of many years, following all of the classical symptoms of ulcer of the stomach.

(2) *Fibrotic stenosis.* (*a*) *General* and (*b*) *localized.* (*a*) *General gastric fibrosis* described by Brinton and Hanot may lead to far-reaching change in the mucous and submucous coats of the stomach, invading the pylorus as the process advances, causing a marked contraction and thickening of the entire organ with almost complete closure of the stomach outlet. In some of these cases the mucosa is so involved as to give many of the symptoms of atrophic gastritis with marked anemia, consecutive change in the secretory, motor and absorptive functions of the stomach. The organ is small, may present as a globular tumor, holds but little fluid. The use of the stomach tube gives valuable information. In some of these cases it is impossible, because of the thickened stomach wall, to inflate the organ. The differentiation of these cases presents great difficulty. They often resemble infiltrating cancer of the stomach.

(*b*) *Localized fibrous thickening of the pylorus,* likely to be annular, is occasionally found following previous conditions which may have given rise to but few symptoms and which were not dependent upon preceding ulcer. In these cases the ring-shaped constriction causes consecutive dilatation with its attending symptoms. It is not easy to palpate this small thickening of the pylorus in the majority of cases.

(3) *Hypertrophic stenosis, as described by* Cruveilhier and recently considered in detail by Boas, occasionally presents for diagnosis and treatment. We have seen this condition only at rare intervals, and where suspected we have not always felt that the diagnosis was correct. These cases are supposed to follow chronic gastritis with ultimate dilatation, in which the muscular and submucous tissue as well as the mucosa are finally sufficiently changed to give rise to constriction of the pylorus.

(4) *Stenosis dependent upon ulcer.*—Ulcer at or near the pylorus and in the first part of the duodenum with associated spasm, marked swelling which may be acute or due to secondary inflammation is unquestionably an occasional cause of pyloric stenosis. The pain is likely to be most severe as the food is ready to leave the stomach. An examination of the stomach contents materially aids in reaching satisfactory conclusions. In these cases the pain is out of all proportion to other complaints, there may be hemorrhage, with many other symptoms, subjective and objective of ulcer.

(5) *Acute inflammatory stenosis associated with infection, deep-seated gastritis and acute poisoning,* presents a train of symptoms coincident with these acute conditions, yielding as the associated inflammation subsides unless the changes are sufficiently deep to give rise to permanent lesions.

(6) *Syphilitic stenosis,* as described by D'Ursi and mentioned by others who have written on specific stomach diseases, is occasionally found with clinical features which do not permit of differentiation from other forms of cicatricial or inflammatory stenosis, save as we get authentic histories and, better still, results from antisyphilitic treatment.

(7) *Tuberculous stenosis* is occasionally associated with far-reaching disease of the stomach. Individual clinical experiences with this complication will always remain limited.

(8) *Stenosis dependent upon non-malignant growths,* fibromyoma, adenoma and polyp, described by Bouveret, Cornil and Chiari, only rarely found, may prove puzzling; the diagnosis can be made during life only after exploratory operation.

(9) *Stenosis due to distortion or traction,* giving rise to acute pyloric obstruction (Kussmaul, Albrecht and Riegel) dragging at a point in the

horizontal part of the duodenum by the weight of the stomach contents where the former merges into the vertical duodenum, firmly fixed against the spine, is relieved at once by emptying the stomach with the tube or by free vomiting. This condition is occasionally responsible in all probability for acute and alarming dilatation.

Extrapyloric Stenosis.—It is difficult to divine all of the unusual and unexpected conditions which may lead to extrapyloric organic stenosis. We never cease to wonder at these pathologic possibilities. Clinical and pathological experiences in this field are rarely repeated. Perigastritis, gall-stone disease, adhesions to neighboring organs, particularly to the liver and gall-bladder, distortions due to innumerable anomalies and pathologic changes invading the organs already mentioned, the pancreas and kidney, may produce narrowing of the pylorus, consecutive dilatations and all of the symptoms of pyloric stenosis. In a paper written a number of years ago on the "Vagaries of Gall-stones," the writer reported a case in which monstrous gall-stone masses with associated adhesions caused all of the symptoms of pyloric construction during an entire year. At the end of this time the hard tumor disappeared, for a few days symptoms of complete intestinal obstruction followed, preparation was made for operation, when nature came to the rescue. Gall-stones resembling cobbles in size were passed by the rectum and the patient, a woman advanced in life, made a perfect recovery and is still living, without a return of symptoms.

In the majority of cases, extrapyloric stenoses are recognized, though the pathological condition giving rise to these may not be determined. Perigastritis, peritonitis, perihepatitis, pressure due to pancreas tumors, large kidney masses and matting together of organs may be suspected as causes of extrapyloric stenosis.

In our study of the cases under consideration we must (1) give data which prove the presence of pyloric stricture, and (2) its benign nature must be established.

1. It is rational to suspect stenosis of the pylorus, whenever it is possible to demonstrate marked dilatation of the stomach with perceptible lowering of the greater and lesser curvature, recurring peristalsis from left to right (peristaltic unrest), which may or may not be painful, and may be and frequently is associated with ballooning of the organ; with either a palpable mass or thickening at the pylorus, more or less splashing and evidences still further of motor insufficiency, the latter made positive by means of the stomach tube, and such other refinements of diagnosis as are now used by all who study these cases closely which prove beyond peradventure the stagnation of food. *The fasting stomach found distended and containing food remnants must always arouse suspicion.* Stomachs may be abnormally large yet true ectasia with motor insufficiency may be absent. Megalogastria does not mean motor insufficiency or the inability of the stomach to perform its functions with fair satisfaction. Mechanical obstruction implies motor insufficiency sooner or later and this means inability of the stomach to empty itself with all attending subjective and objective symptoms. Stenosis present, the dilatation which is secondary remains, it is a permanent deformity. A stomach which is able to empty itself, but for some reason becomes dilated (true primary dilatation), does not remain permanently dilated as a rule. It is irrational to conclude that all enlarged stomachs are insufficient and that their pylori are stenosed. This physical condition must be associated with a knowledge of disturbed function before accurate conclusions are justified. Pyloric stenosis creates a decided disproportion between the stomach's task and its ability to perform. "Wo Arbeitslast und Arbeitskraft (as Riegel so prettily expresses it), einander nicht mehr, wie in der Norm, das Gleichgewicht haben." This fact explains all of the conditions consecutive upon mechanical obstruction at the stomach outlet. Alkaline contents are as a rule hurried through the stomach and, contrary to general belief, far-reaching change as in achylia gastrica shows no tendency to gastrectasia. We must always be suspicious, where there is motor disturbance with hypersecretion and hyperacidity, of existing stenosis. In these cases it may often be difficult to decide, in spite of evidences of stenosis and dilatation, whether the former is the cause of the hypersecretion. Not all benign stenoses are associated with hypersecretion.

One of the leading symptoms of stenosis is vomiting. Frequency and quantity of vomited matter vary in accordance with the size of the stomach and the degree of constriction. In advanced cases the quantity of vomited matter is as a rule greater than the quantity of food and liquid taken. The vomited matter with obstruction, shows the presence of food long since taken. Vomiting relieves these patients, a load has been removed, it is wonderful to see how encouraged they are, while this enormous pocket is filling only to empty itself again. The reaction of the fluid vomited, its appearance, odor and color depend entirely upon the nature of the underlying disease. Associated with this vomiting at intervals, which may indeed be considered the leading symptom of stenosis, is marked change in appetite, sometimes perverted, fickle or completely lost. Intolerable thirst with symptoms of stenosis, in spite of the fact that the stomach is receiving fresh water for its relief, is always suggestive that this is of high degree. In these cases there is monstrous gastrectasia.

As the secondary changes follow, the tongue becomes glazed, often dry, coated at times, or remains unchanged. Constipation is the rule. The general appearance of the patient suffers, malnutrition, malassimilation are soon shown with all the other ear marks of the disease.

Peristaltic unrest, recognized if the abdomen is sufficiently watched, even during the early stage of the disease, becomes a symptom of great value. Peristaltic unrest may continue with marked stenosis until the patient is far advanced in the disease, when the musculature of the stomach wall becomes so feeble as to refuse longer to make the effort to empty itself, or when, with degeneration and infiltrating disease, it finally ceases. Often, in cases of stenosis, peristalsis is materially increased or aggravated during the early stages by the administration of soda and tartaric acid as carbonic acid is released. Splashing is usually present; to be of value it must be associated with other symptoms and we must make sure that it is due to retained stomach contents. As a rule these patients are able to produce the characteristic sounds without the assistance of the physician. Physical examination of the stomach including usual methods, often gives valuable data and must be practiced to confirm subjective symptoms.

The stomach tube as a diagnostic agent is indispensable. It is necessary in order to gauge the degree of obstruction and the amount of insufficiency to know the length of time food is held in the stomach. In none of these cases are we to neglect the inflation of the stomach, either through the tube or by carbonic acid liberated by the administration of a sufficient quantity of sodium bicarbonate and tartaric acid. Simple as is this maneuver we may occasionally misinterpret the result. I recall a case in which inflation filled the abdomen with what was considered a dilated stomach, in which the colon was distended through a gastrocolic fistula. The case proved to be one of infiltrating malignant disease of the stomach communicating with the colon as a result of ulceration and adhesive localized peritonitis.

The urine presents changes which cannot be ignored. Its quantity is reduced, it is concentrated, likely to be alkaline and contain indican.

Tetany is a symptom of very great value in the diagnosis of gastrectasia dependent upon any of the causes enumerated. In spite of all that has been written on this subject the characteristic cramping and other alarming conditions in the majority of cases, this symptom is not always correctly interpreted and the average physician, because of its comparative infrequency, fails to appreciate its significance. I make this positive statement because of the very painful experiences which I have had in consultation practice. Symptoms referable to the nervous system, particularly neurasthenia, are frequent and predominate in cases of benign stenosis.

The heart, as the disease advances, may become ungeared, may partake of the general neurotic condition of the patient or may simply show increasing weakness with advancing disease. The presence of tumor positively connected with the pylorus or duodenum and symptoms of gastrectasia gives positive information.

If there is no tumor it may be difficult to decide between primary and secondary dilatation. In both conditions the subjective symptoms may be the same. In both we have seen peristaltic unrest and even bile in abundance mixed with the stomach contents with marked organic obstruction. In many of these cases, where repeated examinations of the stomach contents and close observation of physical signs have failed, we have applied the therapeutic test for purposes of diagnosis. We need not hesitate to subscribe to the statement of Mintz, Bouveret and Bevic that this often furnishes the only positive diagnostic means. Regulated diet, lavage of the stomach, alkalies in proper doses to meet underlying hyperacidity will, in primary dilatation be followed by material improvement, long periods of relief and partial return of motor sufficiency, as is shown by the tube and other tests. The alkalies probably relieve associated spasm. Such improvement with even temporary disappearance of symptoms we have never noted with true organic stricture of the pylorus, whether benign or malignant. It must be remembered that the quantity of retained ingesta and secretions are less in primary than in secondary dilatation, also that primary dilatation may recur with renewal of original symptoms. The presence of bile in large quantities with evidences of constriction would indicate its location below the papilla in the duodenum. The neurasthenic element is much greater in cases of primary than of secondary motor insufficiency.

2. What are the distinctive clinical features which justify the conclusion that the stenosis is benign?

Previous History.—Whatever the suspicions, there is no stronger link in the diagnostic chain than the knowledge gained by painstaking inquiry into the previous histories of these patients. In both men and women the incidents of childhood and puberty as well as the suffering of mature life demand most thorough investigation. It would be an insult to your intelligence if I were to rehearse the data which such study reveals. Included are the clinical pictures of the many primary conditions which have finally led to stenosis. Patients find no difficulty in recalling these; they cover, as a rule, long periods of suffering which have left indelible impressions. A patient with final stenosis and gastrectasia depending upon ulcer has never allowed the sequence of symptoms to fade from his memory; neither has the patient who suffers from perigastritis, far-reaching adhesions with gall-stone disease, forgotten the early or late attacks. Time and patience only are required to hew a way out and through this quarry to the open light. Our results are sufficient to reward the effort. Failures in diagnosis, particularly of the conditions under consideration, are too often the result of hurry and lack of attention to detail.

The *age* of the patient is an important factor.

The more advanced in life, the more likely is the stenosis to be malignant. This rule has its exceptions but they are few. Malignant disease presents a much shorter clinical history. While this may occasionally have latent periods, it is the exception. Chronicity with a long train of symptoms argues against malignancy. The symptoms of malignant stenosis are as a rule continuous, there is less likelihood of long periods of relief or marked periods of exacerbation. The wasting of the patient, the increasing muscular enfeeblement go hand in hand. The blood conditions are entirely different. If there is associated anemia and this is out of proportion to the cachexia, with evidences of dilatation, we are not as a rule dealing with carcinoma.

Heredity must always play an important rôle in the etiology of pyloric cancer. Benign constriction with palpable pylorus presents a much smaller tumor than does cancer. Whether this thickening is due to intra or extra pyloric involvement, there is never such characteristic nodular feel nor is there such suggestive hardness and resistance nor is the mass usually as large as in cancerous disease. Physical examination of neighboring organs and distant glands gives data of great importance. Distant glands as well as those in the abdomen need thorough investigation. Thus Troisier, several years ago, and Pitt in a recent article in the *Practitioner* (April, 1905), have called attention to the enlargment of the glands above the clavicle, particularly behind the left sternomastoid, in pyloric and stomach cancer. Rapidity of growth is characteristic of malignancy. The use of the stomach tube, the examination of the stomach contents, chemical and microscopical, give information which the evenly balanced clinician will add to such other facts as have been made clear by thorough study. It will frequently be possible to recognize by these added physical methods early organic change at the pylorus. Much has been said of the value of free HCl. in the diagnosis of benign and malignant disease of the stomach. I feel that I have no right to repeat on this occasion the results of chemical analysis of the stomach in detail which furnish us with facts for differentiation. There are, however, a few facts which it may be wise to give to the profession in connection with a paper such as is here presented. They are the following:

Stomach contents which show gradual loss of HCl. from time to time, with the addition of organic acids as the free HCl. disappears, evidences of fermentation, must lead to a strong suspicion of malignant disease. It occasionally happens that cases of pyloric cancer continue to show free HCl. to the end. Gradually fading hydrochloric acid, according to Jaworski may be due to the transition of non-malignant to malignant disease as well as to the gradual development of achylia gastrica in cases of mucous gastritis with more or less stenosis at the pylorus. This same change may also take place while malignant disease develops in the scar of an old ulcer and in the included tissue of a non-malignant ulcus ventriculi. Gluzinski makes the following statement: "If it were possible to recognize the transition of an acid gastritis into the mucous form and if, at the same time, it were possible to recognize that this change is due to the formation of a neoplasm and not to the simple cicatricial healing of an ulcer, then it would be possible to make an early differential diagnosis of malignancy." To accomplish this, Gluzinski makes three examinations of the stomach contents, one following the other on the same day. He first examines the remnants of the stomach contents early in the morning. The stomach is thoroughly emptied, chemical and microscopical examinations are made. The organ is then thoroughly washed, egg albumin is given; this is expressed after three-fourths of an hour. At noon beefsteak is given to be followed by the final emptying four hours later. These examinations are repeated several times at intervals of two or three days. If remnants of food are found in the stomach after fasting the question arises whether this is due to the simple atony of the stomach wall or mechanical obstruction, and we are thrown back to the same necessities of observation as before. Gluzinski places great importance upon the fact that with benign stenosis, particularly associated with ulcer, and its cicatrization, we find free HCl. present in varying quantities in all three examinations. It may be assumed that if at the first test, food remnants are found, at the second there is absence of HCl. or only faint presence, and after the beefsteak test marked reduction or complete absence of HCl. with lactic acid and bacteria, the stenosis may be considered malignant. If we find blood with the stomach contents in the wash water with particles of tumor, the diagnosis becomes easy. Lactic acid may be present with achylia gastrica, associated with chronic gastritis, especially when these conditions have more or less stenotic accompaniment. In pernicious anemia, lactic acid is sometimes present with gastrectasia. Here the blood picture must differentiate. It is a rule which cannot be too often repeated that with malignant disease the cachexia is out of all proportion to the anemia, whereas, in those forms of pernicious anemia with gastrectasia and atrophy, the anemia is out of proportion to all other symptoms.

The valuable reports which have reached us from Cohnheim's clinic, many of which are repeated in a paper recently published by Ackermann and Gompertz, which deals with the microscopical examination of the fasting stomach contents and its diagnostic value, when put into practice, added to the knowledge gained by chemical examination, give strong evidence which justifies more accurate differentiation during the incipient stages of the conditions under consideration. The microscopical examination of the stagnant stomach contents with the presence

of HCl. shows, in cases of hyperacidity and hypersecretion that the muscle fiber is partially digested, that the striae have more or less disappeared, that starchy food is not changed. Yeast cells are found in the stomach contents with stagnation. Observers find these in chains and when the stenosis is benign these are accompanied by sarcinæ. Sarcinæ are not found unless the stomach contents contains HCl. Hence, their presence argues, as a rule, in favor of benign stenosis save in exceedingly rare cases of ulcus carcinomatosis. In this latter condition, the test of Gluzinski added, will give valuable information and as the disease advances, if malignant, there will be a gradual decrease of HCl. and sarcinæ; finally, both will be absent when the HCl. is found replaced by lactic, acetic and butyric acids, the sarcinæ by the Oppler-Boas bacilli. The microscopical appearance when the disease is malignant shows quite a different picture. Cohnheim asserts that "about 99 per cent. of the cases with stagnation and Oppler-Boas bacilli or lactic acid are pyloric carcinoma, the remaining one per cent. being either gastritis gravis or a carcimona in the vicinity of the pylorus." Ackermann and Gompertz in their résumé make the statement that "Constant presence of pus, blood and possibly infusoria in the fasting stomach contents is absolute evidence of extrapyloric carcinoma." Still further, "Benign obstruction can be diagnosed early by the finding of sarcinæ, yeast cells in chains, or food remnants." "The early diagnosis of malignant obstruction of the pylorus can be made by the finding of the Oppler-Boas bacillus." There is no pathognomonic symptom of cancerous stenosis.

Large quantities of indican in the urine, an abnormally high urea output are always suggestive of malignancy. The more we deal with the diagnosis of these conditions, the more convinced are we that no other organ requires longer observation than does the stomach, before reaching conclusions which justify diagnosis. I know of no better dictum to place before the student and the hesitating practitioner than that of Leube to which we may unhesitatingly pin our faith in the differentiation of the conditions under consideration. I do not apologize for repeating it here. "Cancer of the stomach is present in all probability if the unquestionable stomach disease has attacked a patient between fifty and sixty years of age who formerly digested all food well. If such a person becomes dyspectic without an evident etiological factor, it may be assumed with considerable certainty that he is developing a gastric cancer." If this fact were better appreciated there would be a large addition to the credit side of accurate and early diagnosis.

Treatment.—When an internist, as conservative as was the late lamented Riegel, makes the following statement, "Gastrectasia following stenosis must be relegated to the field of surgery; in these cases operative interference alone leads to cure," any consideration of medical treatment would seem almost unnecessary. Our surgical friends have established the fact that surgery scores its greatest successes in the treatment of the conditions under consideration, and it is these cases that the internist must refer to them for permanent relief with encouraging and increasing confidence. Our labor will end in cases of extreme benign stenosis as soon as the diagnosis is made. There will always be cases, however, in which for some good reason, either because of moderate stenosis with the hope of ultimate compensatory hypertrophy and a sufficient gastric function, because of inherent weakness in congenital cases, complications in the adult contraindicating operation, or the refusal of the patient to submit to radical treatment, the physician will be expected to relieve symptoms and make the lives of these patients as comfortable as his art can make them.

Prophylaxis.—Little need be said on the subject of prophylaxis, for little can be done. It is wise to warn patients with ulcer and chronic gastritis against carelessness and it will be the duty of the physician to give such directions as will lead to lasting cure, including the avoidance of food bolting, overeating, dissipation, giving at the same time thorough instruction in such hygienic measures and methods of living and eating as lead to an improved resistance. Further, we must warn the patient against the overloading of the stomach after long periods of restricted diet or after conditions which have led to inanition. The following indications for the medical treatment of benign stenosis of the stomach seem justified:

1. *Such foods only to be taken as the dilated stomach with motor weakness can prepare to be forwarded beyond the point of resistance for further digestion.* The volume of food must be small, concentrated and thin. Diet in these cases can only be rationally prescribed when we depend for our indications upon the degree of stenosis and the absolute or relative weakness of the muscle. The indications are offered by the free use of the stomach tube, the examination of the stomach contents early and late, and the microscope. Foods must be given with a thorough understanding of associated secretory anomalies. It is far better to allow these patients to eat at short intervals, giving but little at a time, than to overload the stomach with the ordinary three daily meals. The quantity and quality of food can be easily determined if the physician will give this matter sufficient time. Experience teaches that in cases of extreme dilatation thirst is by no means relieved by the inordinate use of liquids. Von Mering has again emphasized the fact that fluids are not readily absorbed by the stomach. In these cases the stomach is still further distended by the excessive use of fluids which serve simply to deplete the patient still further by determining an extra supply of blood

to the organ, thereby increasing hypersecretion, aggravating nervous symptoms and occasionally provoking tetany. On the other hand, solid or dry food refuses to pass the obstruction. It is, therefore, wise to pursue a safe middle course, giving foods in concentrated mushy liquid form. For this purpose such liquids should be chosen which will serve to carry other articles of food readily digested and absorbed. Thus bouillon, chocolate, cocoa and milk in small quantities may serve as vehicles for eggs, meat solutions, stale bread, plasmon, somatose, Mosqueras' beef meal, tapioca, arrowroot, rice and many other articles of diet which will occur to the physician as he studies the case. The various gruels and beef juice properly prepared, meat essence, Leube-Rosenthal food, scraped beef, broiled fish, sweet bread, custard, omelet, moderate amount of butter, milk toast, Zwieback with milk, potato puree, spinach and squash are all borne in most cases. There are but few cases associated with hypersecretion and hyperacidity in which food passes the pylorus, aided by such methods as we have at our command, which do not bear scraped raw beef well and to this, with eggs and liquids in small quantities the writer has often pinned his faith with encouraging results. A moderate amount of coffee at breakfast is allowable in the majority of cases. Stimulants are contra-indicated save in extreme conditions. These patients need to be kept under perfect control. For this reason sanatorium or hospital treatment offers most encouragement. In many functional stenoses the use of olive oil or the emulsion of sweet almond oil, as recommended by Cohnheim, serves not only as a food, improving the general condition of the patient, but it seems to relieve spasm and friction. Rectal feeding is sometimes necessary.

2. *Seek to prevent stagnation of food with associated fermentation and the formation of organic acids.* This can best be done by the use of the stomach tube. In these cases lavage does yeoman's service. In the majority of advanced cases the stomach should be washed out twice daily, its contents siphoned at various depths, the tube introduced deep enough to relieve the stomach. Sufficient water should be used. A thorough knowledge of the shape and position of the stomach offers valuable indications for the successful use of the tube. Clean warm water without the addition of drugs is sufficient. Both in functional and organic cases the final flushing with cold water at a temperature of 50° F. seems to exert a tonic influence over the stomach and its musculature, in cases where the stenosis is not extreme. In order to get good and lasting results, this part of our work must be thoroughly done. Carelessness and undue haste or the empiric use of the tube can lead only to indifferent results. *Rational diet founded upon the knowledge gained by the use of the stomach tube and the microscope, with thorough lavage, become the most telling factors in the medical treatment of benign pyloric stenosis.* The accidents following daily lavage in these cases have been so few as not to discourage the treatment which most of us have found fairly successful.

3. *Assist so far as it is possible in the emptying of the distended stomach.* The methods already suggested with cautious massage, room gymnastics, the use of electricity (to which too much confidence has been given by some), with thorough attention to details and the use of drugs, such as shall be mentioned, are all that can be done to meet this indication.

4. *Prevent tetany and other nervous and distant symptoms.* Overcome neuropathic tendencies and conditions in functional stenosis leading to spasm. The writer is fully convinced that he has seen cases of tetany in which symptoms have been postponed by the timely emptying of the stomach. At the present time he has under observation a patient who refuses surgical interference, with benign stenosis, monstrous dilatation, hypersecretion and hyperacidity. Tetany can be promptly produced by the neglect of thorough lavage. It matters not what theory we adopt concerning the production of tetany, the fact remains that the majority of cases are associated with monstrous dilatation, residual stagnant food and hypersecretion. All facts warrant the prevention of such accumulation. Methods which overcome neuropathic tendencies and conditions which lead to functional stenosis require a thorough consideration of all that these cases present, attention to hygiene, exercise, diet and much detail which must of necessity occur to the thinking therapeutist.

5. *Improve the general condition of the patient and hold this at par or above par whenever possible.* This includes all of the methods already considered with such tonic treatment, moral suasion, change of air and scene as are indicated by the individual cases.

6. *Treat associated symptoms as they arise by rational and natural methods, including the use of drugs, attempting by these to overcome or counteract the effect of secretory and motor anomalies.* These indications cover a broad field of activity. Guard against pernicious activity. There is a strong tendency in the treatment of these conditions toward polypharmacy. The use of the alkalies and such remedies as act upon the secretions of the intestines and their musculature causing free movement of the bowels which tend to remain constipated, are indicated in many cases. Repeated tests give indications for the administration of alkalies or acids. With hypersecretion and hyperacidity we have recently had excellent results from the use of suprarenal extract and belladonna, combined with mechanical treatment and alkalies. With peristaltic unrest and functional stenosis, belladonna, gelsemium and cherry-laurel water have frequently relieved symptoms. Eserine and the remedies above-mentioned have relieved associated flatulence and

belching of gas. Strychnine, nux vomica and the bitter tonics have in many cases served to tone the patient and relieve symptoms. Spasm has sometimes been relieved by the use of small doses of atropine, the faradic current as recommended by Kussmaul; only rarely have we resorted to codeia. Recently, encouraged by an article from the pen of Haas-Brunn in the March number (1905) of *Die Therapie der Gegenwart* on "Eumydrin, ein Atropin-Ersatz, in der Therapie der Magen- und Darmkrankheiten," we have used the drug with some success. In no case has it been used long enough to offer positive conclusions. Resorcin, bismuth salts, benzonaphthol, Carlsbad salts and physol, made according to Merck's formula, may be used for the relief of troublesome symptoms.

With thiosinamine recently suggested, to be used hypodermatically (10 per cent. glycerin and water solution) and with the use of scopolamin the writer has had no experience. The galaxy of remedies suggested in our text-books proves conclusively that there is no single remedy upon which we can rely for the treatment of symptoms associated with stenosis of the pylorus. Rational and natural therapy, made as simple as possible, will prove most satisfactory.

ON THE RELATIONS OF SOME OF THE METABOLIC DISEASES TO INTESTINAL DISORDERS.*

BY THOMAS B. FUTCHER, M.B. (TOR.),
OF BALTIMORE, MD.;
ASSOCIATE PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

WHEN I was asked to contribute a paper on the relation of certain metabolic diseases to intestinal disorders, I consented to do so with some hesitation. I fully appreciated the fact that the well-being of the individual was intimately connected with the proper carrying on of the normal intestinal functions; also that many of the ailments the human organism is subject to are dependent upon derangements in the intestinal canal. My hesitancy was mainly due to the fact that I realized that but few, if any, of the diseases we are accustomed to designate as metabolic in origin, such as gout, diabetes, etc., are due essentially to disorders in the intestine. On considering the matter, however, I recalled that some of the more obscure and rare metabolic diseases have been attributed by investigators to disturbances in intestinal function. I thought that a review of some of the main facts concerning these diseases, particularly regarding alkaptonuria, ochronosis, and cystinuria, might be of interest to the members of the association.

I. Alkaptonuria and Ochronosis.—Alkaptonuria was first described by Bödeker[1] in 1859. The characteristics of the urine in this condition are briefly as follows: When voided it has a normal appearance, but rapidly acquires a deep-brown color and ultimately becomes black on exposure to the air. The brown color is greatly intensified by the addition of an alkali, its development being accompanied by the absorption of oxygen from the air. The urine is of normal specific gravity. It reduces alkaline copper sulphate solutions with the aid of heat, the mixture at first being of an inky-black color. Ammoniacal silver nitrate solutions are reduced in the cold. It does not reduce alkaline solutions of bismuth. The urine does not ferment with yeast, and it is optically inactive. The addition of a ferric chloride solution produces a transitory bluish-green color. Diapers and linen moistened with the urine turn a deep brown color on exposure to the air.

Bödeker called the substance which produced these interesting urinary changes alkapton (from "alkali" and "καπτειν," to absorb freely), owing to the property that urine containing it possessed of rapidly absorbing oxygen from the atmosphere in the presence of an alkali. He did not isolate the substance. It was not until 1891 that Baumann and Wolkow[2] demonstrated that the peculiar reactions of alkapton urine were due to the presence of homogentisic acid (Homogentisinsäure, $C_8H_8O_4$ or $C_6H_3(OH)_2.CH_2.COOH$, which is the dioxyphenylactic acid derived from hydrochinon. This acid has been found in practically all the cases reported subsequent to that date and in the urine of some of the cases previously reported, and is now conceded by all observers to be the cause of the urinary changes in alkaptonuria. The lead salt of the acid, lead homogentisate, is easily obtained by heating the urine nearly to the boiling point and adding five or six grams of neutral lead acetate to each 100 c.c. of urine and allowing it to cool for twenty-four hours. The lead salt crystallizes out in the form of brownish, stellar-shaped, acicular crystals, watery solutions of which give all the reactions of the original urine. The acid itself crystallizes with one molecule of water in large, transparent, prismatic crystals, which become non-transparent at the temperature of the room with the loss of the water of crystallization. They melt at 146.5° to 147° C. They are soluble in water, alcohol and ether, but nearly insoluble in chloroform.

The question now arises, what is the source of the homogentisic acid? It is this side of the consideration of alkaptonuria which brings it into bearing with the subject under discussion. Baumann, Wolkow and Embden, and others, believe that homogentisic acid is derived from tyrosin. Tryosin ($HO.C_6H_4.C_2H_3(NH_2).COOH$), or amido-oxyphenylacetic acid, is a normal product of trypsin digestion of proteids in the upper part of the intestinal tract, being formed by a hydrolytic cleavage process. The above-mentioned investigators have shown that when tyrosin is fed by mouth to an alkaptonuric individual nearly the whole of it is excreted as homogentisic acid, whereas the acid is not excreted in the urine when tyrosin is ingested by a healthy person. Beyond the fact that tyrosin and homogentisic acid

* Read before the American Gastro-Enterological Association, New York, April 24, 1905.

are both aromatic acids, the two have nothing special in common, although of somewhat similar chemical constitution. The conversion of the former into the latter involves a shifting of the hydroxyl groups of the benzene ring; in other words, a simultaneous oxidation and reduction within the molecule. The view generally held regarding the etiology of alkaptonuria is that originally advanced by Baumann and Wolkow, who thought that the conversion of tyrosin into homogentisic acid is due to bacterial activity, and consequent putrefactive conditions in the upper intestinal tract. They even suggested that there might be a specific bacterium in such cases.

Some clinical facts regarding alkaptonuria may not be without interest. It is congenital in the vast majority if not all of the cases. In a good many of the cases a history is obtained that the individual's urine in infancy stained the napkins a dark-brown color. It persists throughout life. That it is rare is demonstrated by the fact that A. E. Garrod[3] found that only 40 cases had been reported up to 1902. Four of these were reported from the United States, one by myself in 1898. The condition predominates in males. Of the 40 cases, 29 were males and 11 females. The anomaly is likely to make its appearance in two or more brothers and sisters whose parents are normal and among whose forefathers there is no record of its having occurred. There is only one recorded instance of alkaptonuria having been transmitted from an affected parent to a descendant. This occurred in one of two sons of the patient with alkaptonuria I reported.[4]

The investigations of A. E. Garrod have thrown new light on the subject and given us a new conception of the anomaly. As a result of his research he finds that a very large percentage of the cases, concerning which he has been able to collect data, occurred in individuals who are the offspring of the marriage of first cousins, who do not themselves manifest the peculiarity. He points out that in this respect alkaptonuria resembles albinism and possibly also cystinuria. He has advanced the view, therefore, that alkaptonuria is a "sport" or alternative mode of metabolism, congenital in origin and persistent throughout life. In favor of this view is the fact that each individual excretes from day to day a very constant amount of homogentisic acid, the variations being within narrow limits and easily explained by fluctuations in the amount of proteid food taken from day to day. The average daily excretion of the acid has ranged between 2.6 grams in a child three and one-half years old and 5.9 grams in a young man of eighteen years. One would reason, therefore, that alkaptonurics suffer from some inherited metabolic defect, and it seems probable that this defect is closely related to the metabolism of tyrosin. This conception necessarily modifies the view previously held that alkaptonuria results from putrefactive changes in the upper intestinal tract. Being apparently a congenital anomaly, it does not seem possible that it is due to abnormal bacterial activity in the intestine. It does not, however, weaken the view that it is associated with some intestinal digestive disturbance. It would appear that there is some congenital defect in proteid digestion in the intestine whereby homogentisic acid is formed instead of tyrosin.

The general health of alkaptonurics appears to be in no way impaired. Until a very recent date, the only clinical significance that alkaptonuria was thought to possess, rested on the fact that a number of the cases, before recognition, have been mistaken for diabetes mellitus, owing to the power the urine possessed of reducing alkaline copper solutions. The fact that the urine does not ferment, is optically inactive and does not reduce bismuth, together with its peculiar color on standing and on the addition of an alkali, should have obviated such a mistake, however.

Recent observations indicate that a pathologic condition of great interest and rarity is associated with and probably due to the metabolic disturbances in alkaptonuria. This is the remarkable affection known as "ochronosis" or pigmentation of the cartilages, first described by Virchow, in 1866. In Virchow's case there was remarkable pigmentation of the cartilages of the body of a man, aged sixty-seven years, who died of the effects of an aneurism. He gave the name ochronosis to the condition owing to the ochre-like discoloration of the cartilaginous tissues. Osler,[5] one year ago, reported two cases of ochronosis in alkaptonuric brothers, both of which cases had been previously reported in the literature as alkaptonurics, one by Marshall and the other by myself, and constituting two of the four instances of alkaptonuria observed in this country. Previous to Osler's two cases, only seven instances of ochronosis had been recorded. Two of them were described as having "melanuria," but Albrecht,[6] who published the seventh case in 1902, deserves the credit of first suggesting an association between the disease and alkaptonuria. The urine of his patient was dark colored and reduced sulphate of copper solutions, but homogentisic acid was not absolutely demonstrated.

Osler's first case was a man fifty-seven years of age and was the alkaptonuric I reported. The sclerotic coats of the eyes showed areas of pigmentation on the exposed portions. The cartilages of the ears, particularly the concha and helix, presented a remarkable blue-black discoloration. A noteworthy feature not previously recorded was that a butterfly-shaped area of the skin over the nose and cheeks was also remarkably pigmented, the pigmentation very closely resembling powder marks. The discoloration of the sclerotics and of the ears was present, but less marked, eight years ago. There was a very marked bowing of the spine with the convexity backward and he walked with a marked stoop of the shoulders. The patient has been under my own observation for some time and he occasionally has some stiffness of the knee-joints in

which there is marked crepitation on passive movement. The pigmentation of the cartileges of the metacarpo-phalangeal joints has recently been evident through the skin over the knuckles. The other brother, forty-nine years of age, presented a similar but less striking pigmentation of the sclerotics and cartilages of the ears. He had noticed the pigmentation for several years. The patient died of pneumonia but no autopsy could be obtained. There is little doubt but that the deep-seated cartilages of both these cases would have manifested the same changes.

The probabilities, therefore, are that ochronosis is another manifestation of the metabolic disturbances in alkaptonuria, which previously had been recognized only by the urinary changes. There is no definite evidence that the ochronotic condition in any way affects the health or the body functions. It is worthy of note, however, that in one of Osler's cases the joint affection objectively simulated conditions found in arthritis deformans. Some of the cases of ochronosis have not been associated with alkaptonuria and Garrod is inclined to the view that there may be two distinct groups of cases. The interesting fact is that Ogden's alkaptonuria case, another of the four American cases, has recently been found to have the ochronotic pigmentation. Whereas all alkaptonurics do not have ochronosis, it will probably be shown eventually on careful examination that most cases of ochronosis exhibit alkaptonuric changes in the urine.

II. Cystinuria.—Another metabolic affection which has generally been regarded as being dependent on intestinal disturbances is cystinuria, characterized usually by the spontaneous deposition of hexagonal crystals of cystin in the urine. The condition is rare, as shown by the fact that up to November, 1904, Simon and Campbell[7] found that only 131 cases had been reported in the literature. Cystin ($C_6H_{12}N_2S_2O_4$) is the disulphide of di-amido-ethidenelactic acid. According to Baumann and Goldmann a substance similar to cystin occurs in very small amounts in normal urine. This substance occurs in large quantities in the urine of dogs after poisoning with phosphorus. Although it has not been definitely demonstrated that cystin is a normal constituent of the urine of human individuals, yet there is good reason to believe that cystin is an intermediate product of normal metabolism and that it is ordinarily broken up with oxidation of the greater part of its sulphur to sulphuric acid. According to one view cystin is apparently preceded in the course of normal metabolism by cystein. This cystein is regarded as a lactic acid, $CH_3CH.(OH)COOH$, in which one H is replaced by NH_2 and the OH by SH. Cystein is therefore to be regarded as an amidothiolactic acid. V. Bergmann, Simon and Campbell, as a result of their researches, are led to conclude that a certain amount of the cystin liberated during normal metabolism is eliminated in the bile in combination with cholalic acid as taurocholic acid, while the remainder appears in the urine in completely oxidized form.

The clinical significance of cystinuria is not great, because it is commonly unassociated with definite symptoms and may be well developed in persons apparently in good health. Occasionally the individuals have disordered digestions, at times associated with anemia. Cystinuria may be of surgical importance owing to the fact that renal calculi composed of cystin may occur. The crystals of cystin when shaken up with urine present a curious sparkling appearance. The urine on decomposing emits a very offensive odor of sulphureted hydrogen, owing to the large amount of sulphur contained in the cystin molecule. Cystinuria is much commoner in males than in females.

What occasions the development of cystinuria? The view usually held is that the condition is closely related to putrefactive changes in the intestinal tract. Probably the most striking feature at present known to us in connection with the pathology of cystinuria is the almost regular association of the condition with the presence in the excreta of putrefactive basic bodies or ptomains belonging to the class of diamines. The diamines are bodies in which two amine (NH_2) groups are united to a diatomic alcohol radical of the olefine series of hydrocarbons. The diamines of greatest interest in connection with cystinuria are *putrescin*, which is tetra-methylen-diamin and *cadaverin*, which is penta-methylen-diamin. These were found in the urine in cystinuria by Baumann and Udránszky as well as in the intestinal contents, while under normal conditions they are not present. Hammarsten thinks that a connection probably exists between the formation of diamines in the intestine, by the peculiar putrefaction in cystinuria, and cystinuria itself. Herter asserts that it is, on the whole, not unlikely that both the diamines formed by putrefaction in the intestine and the cystin formed in the course of metabolism are the expression of an obscure form of putrefaction in the intestine. It must be remembered, however, that a number of competent observers, among them Cammidge and Garrod, have not been able to demonstrate the presence of these diamines in the urine and feces of the cystinuric individuals they have examined.

The recent view of Simon and Campbell must be mentioned here. It will be recalled that in normal metabolism they think that the cystin of the body is eliminated in the bile in combination with cholalic acid as taurocholic acid, while the remainder appears in the urine in completely oxidized form. They found that while the administration of cholalic acid in the non-cystinuric individual leads to a diminished elimination of sulphur in the urine, this does not occur in the cystinuric subject. This suggests to them that in the cystinuric individual taurocholic acid is possibly not formed at all, in which

case they are forced to assume either that all the sulphur liberated in the body is eliminated in the urine, or that a portion is excreted in the bile in a form different from taurocholic acid.

It is of interest to point out here that A. E. Garrod advances the view that cystinuria, like alkaptonuria and albinism may, on more thorough investigation, turn out to be an example of a "chemical sport." In this connection he cites a most interesting family described by Pfeiffer, which he thinks supports this view. Both parents were normal, but all their four children, two daughters and two sons, were cystinuric. The elder daughter had two children, neither of whom was cystinuric.

III. Diabetes and Gout.—In a discussion of this kind it seems advisable to say something of these two most characteristic examples of metabolic diseases, if only to point out how little dependent they are upon disorders in intestinal function. The writer fully appreciates the fact that many gastro-intestinal disorders occur as symptoms of these two diseases, but time will not permit their being considered here.

According to the latest conception of the disease, diabetes results from disturbances in sugar metabolism owing to deficiency in the production of glycolytic bodies formed in the pancreas and muscles (Cohnheim), and which are necessary for the final combustion of the sugars in the latter tissues. It is doubtful whether intestinal disorders in any way, therefore, play any part in the etiology of diabetes mellitus. The "alimentary" glycosurias are not dependent upon defective intestinal function but rather to the sudden ingestion of some form of sugar in such a large quantity that the liver has not time to convert all the glucose into glycogen, thus storing it up for future use. Consequently the excess passes over into the general circulation producing a hyperglycemia and a resultant glycosuria.

It is possible, according to recent researches, that there may be intestinal influences in the production of one of the auto-intoxications occurring in diabetes, namely acetonemia. The work of Geelmuyden, Schwarz, Waldvogel and Magnus-Levy has shown that acetone is formed largely, if not entirely, from fat and not from proteids as was formerly believed. Schwarz found that in severe diabetics the administration of butyric acid caused a marked increase in the acetone production. Blumenthal and Neuberg demonstrated the interesting fact that only the butyric acid given by mouth, and not that given subcutaneously, caused an increase in the acetone output. They think that it is necessary for the butyric acid to first undergo some change in the intestinal canal and that this may be due to bacterial influences.

So far as we are aware at the present time intestinal disorders play no special part in the etiology of gout. We know so little concerning the causes for the marked disturbances in the nitrogen metabolism in gout that we are not warranted in making a dogmatic statement that disorders in the intestinal functions play no part in the etiology of this disease.

THE IMMEDIATE EFFECT OF BILIARY RETENTION ON THE SECRETORY FUNCTION OF THE STOMACH.*

BY JULIUS FRIEDENWALD, A.M., M.D.,
OF BALTIMORE, MD.;
CLINICAL PROFESSOR OF DISEASES OF THE STOMACH; COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

THE fact that one digestive secretion exerts a marked influence upon another secretion has been known for a long time. Thus George Sticker[1] was the first to show that the saliva exerted a marked influence in the secretion of gastric juice and that this was of such a nature that an absence of salivary secretion not only resulted in an absence of amylolysis but that the proteolysis in the stomach was much retarded thereby. This discovery of Sticker has been confirmed by Biernacki[2] and by myself.[3]

More recently Pawlow,[4] in a beautiful series of experiments on dogs, has shown that the gastric secretion exerts a similar influence on the pancreatic secretion in so far that the former excites a flow of the latter secretion. Observations on the effect of the bile on the gastric secretion have been made by a number of observers. Hayem[5] was the first to show that usually in cases of hypertrophic cirrhosis of the liver a hyperchlorhydria and hypersecretion is found; he did not point out, however, that this condition was in any way connected with the jaundice. Leva[6] too found a similar condition in a few cases of hypertrophic cirrhosis of the liver. N. Kirikow[7] verified Hayem's results. In regard to the gastric chemistry in biliary retention various authors have obtained different results. V. Noorden,[8] Johnson and Behm,[9] Schiff,[10] Kirikow,[11] Malkow,[12] found hyperacidity, whereas Leva,[13] Schneyder;[14] Von Jaksch[15] found subacidity: others found no change whatever (Riegel,[16] Swirelin[17]). The number of observations of these investigators was very small. In addition to this, inasmuch as these writers made as a rule one test of the gastric contents and rarely repeated the examination, they could not obtain a thorough account of the effect of the biliary retention on the secretory function of the stomach. It is a well-known fact that all forms of intoxication of the system can markedly influence the gastric secretion and change its character (Ank-

* Read at the Annual Meeting of the American Gastro-Enterological Association, at New York, April 24, 1905.

indinov,[18] Hanot et Boix[19]). A cholemic condition due to biliary retention is much like the uremic condition due to ligation of the ureter in which marked disturbances of gastric secretion are known to take place (Ankindinov [18]).

The first really systematic examination in this regard was made by S. Simnitzky.[20] He investigated especially cases of catarrhal jaundice, because in this disease the jaundice gradually increases and then gradually again diminishes. Beginning the examinations early and continuing them as the jaundice intensified and as it again diminished, the direct effect of the jaundice upon the gastric secretion could be observed. He investigated the gastric contents of the 12 patients; consisting of 7 cases of catarrhal jaundice, 1 case of Weil's disease, 3 cases of hypertrophic cirrhosis of liver, 1 case of jaundice due to compression of the common duct by a pancreatic cancer. In all 81 examinations were made. He utilized an Ewald breakfast of 35 grams of bread and 250 c.c. of tea.

He found that in those cases in which there was at first a complete biliary retention which gradually began to clear up, the total acidity as well as the percentage of free hydrochloric acid gradually diminished, and that with the retention of the bile the gastric acidity increased in proportion to the degree of biliary retention; the increase in acidity being due mainly to free HCl.

In order to investigate this condition more fully Simnitzky made a certain number of observations on dogs. He performed a gastrotomy according to Pawlow's method and studied the gastric secretion and then ligated the common bile duct and further investigated this secretion. He found that after ligation the acidity of the gastric juice rose markedly, about 50 per cent.

My own observations include eleven cases of which eight were cases of catarrhal jaundice, one of hypertrophic cirrhosis of the liver and two of cholelithiasis; in all 115 examinations were made. In all of our observations we were careful not to include any cases in our list which were accompanied with fever or in which there was any question of an associated gastric catarrh. The gastric contents were examined for the total acidity by titration with one-tenth normal sodium hydrate solution, using phenolphthalein as an indicator; the percentage of free hydrochloric acid was determined in some cases by means of Mintz's method, in others by Töpfer's method. The cases of catarrhal jaundice were mild forms, running their course in five or six weeks. As Simnitzky points out, the variation in the state of the gastric secretion in cases of jaundice can be best observed in catarrhal icterus, inasmuch as the jaundice in this disease develops gradually, reaches a maxium of intensity and again gradually subsides, affording an excellent opportunity to observe the state of the gastric secretion during the varying intensity of the jaundice. In the eight cases of catarrhal jaundice studied as shown in the accompanying tables (See Cases 1, 2, 3, 4, 5, 6, 7, 8), similar results were observed.

The jaundice being slight at the beginning of the attack the increase in the total acidity as well as the free hydrochloric acid is found slightly above normal; gradually as the jaundice increases these factors increase proportionately and again decrease as the jaundice diminishes. So constant is this variation that we can with almost certainty predict from the condition of the acidity of the gastric secretion when the jaundice is about to diminish or disappear.

Case IX of hypertrophic cirrhosis of the liver is very interesting as showing the effect of biliary retention upon the gastric secretion in this disease. The patient, a man of forty-one years of age, had been ill of this disease for four months when he presented himself for treatment. His symptoms were marked, there was the presence of pain in the region of the liver, enlargement of the liver and spleen and an absence of ascites and the jaundice which was at times moderate and at times marked. With a moderate degree of jaundice the total acidity of his gastric contents would be as low as 70 and the percentage of free hydrochloric acid as low as .21 per cent.; while, when the jaundice was marked the total acidity would run as high as 100 and the percentage of free hydrochloric acid as high as .28 per cent.

Of even greater interest in this regard are the two cases of cholelithiasis; both of these cases were common duct cases. They were never accompanied with fever, and jaundice was always present during the attacks which would disappear again in from eight to nineteen days. In both of these cases coincident with the appearance of the jaundice there was an increase in the total acidity as high as 110 and of the percentage of free hydrochloric acid as high as .26 per cent., whereas when the attack of colic had subsided the total acidity would fall as low as 40 and the percentage of free hydrochloric acid as low as .11 per cent.

From our own observations as well as those of Simnitzky we feel justified in concluding that in conditions of biliary retention there is a marked tendency to an increase in the secretion of the hydrochloric acid of the gastric secretion. It is probable, as Simnitzky points out, that this alteration is due to a disease or asthenic state of the secretory cells of the stomach due to poisoning with biliary products.

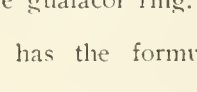
SULPHONATED GUAIACOL COMPOUNDS.*

BY H. C. JACKSON, PH.D.,
AND
GEORGE B. WALLACE, M.D.,
OF NEW YORK.

OF the numberless remedies which have been employed in the treatment of pulmonary tuberculosis, creosote has been for many years one of the greatest importance. It is held by most clinicians that this drug not only checks expectoration and renders it less purulent, but brings about an improvement in the appetite and digestion as well, and in fact exercises a markedly beneficial influence on the whole general condition. Since guaiacol forms from 60 to 90 per cent. of creosote, it is but natural that it be employed as a substitute for creosote. In the past few years it has been used in this way very extensively, and apparently the same beneficial effects are induced by it as the impure mother-substance, creosote. Whether the good results obtained are due to its excretion by the lungs and antiseptic action there or whether they are to be explained by its antiseptic and stimulant action on the alimentary tract, is a question which need not here be discussed.[1] It is known that guaiacol is a somewhat weak antiseptic, although it seems to have a rather pronounced germicidal effect on the tubercle bacillus[2]; that it is excreted by the lungs in small part but chiefly by the kidneys, about 50 per cent. of the ingested guaiacol being found in the urine as an ethereal sulphate, a smaller amount as a glycuronate and some as a more highly oxidized phenol.[3] In the changes it undergoes in the body it resembles carbolic acid, from which, indeed, it differs but slightly chemically. Like the corresponding compound of carbolic acid, guaiacol ethyl sulphate is non-toxic. As a therapeutic agent guaiacol has a number of objectionable features. The form in which it exists—a fluid almost insoluble in water, its taste and odor and its irritant properties, often producing gastric disturbance and making its use by subcutaneous injection a rather painful process, are disadvantages which have stimulated chemists to attempt to make synthetic derivatives, which, possessing the beneficial guaiacol action, are without its disagreeable features. In the past few years a number of guaiacol derivatives have been introduced and extensively advertised by manufacturing chemists. Needless to say flattering clinical reports, each as a rule consisting of observations on a very limited number of cases, have followed. Guaiacol carbonate may be taken as an example. This substance has the formula $CO(OC_6H_4OCH_3)_2$. It is a crystalline powder, insoluble in water, and practically devoid of the irritating properties of guaiacol. Eschle[4] has shown that the compound is broken up in the intestine and from 22 to 66 per cent. guaiacol set free. Still more recently certain compounds have been made in which guaiacol exists in the form of a sulphonate, the sulphur atom being linked directly to a carbon atom of the guaiacol ring. Thiocol is one of these, and has the formula



This substance is crystalline, free from irritant properties, and quite soluble in water. It has been warmly recommended by a number of practioners. A compound of this chemical nature is, according to the pharmacological standpoint, nearly certain to be worthless, since it is common experience that the introduction of the sulphon group into an aromatic group, renders a previously active substance inert and non-toxic, and that the substance is absorbed, circulates in the body, and is excreted without being split up to any appreciable degree.[5] In order that such a combination possess the typical guaiacol action it must either be antiseptic and irritant itself or else be broken up in the intestine or in the tissues after absorption in such a way that guaiacol is set free. If the compound is not antiseptic and is non-toxic, and passes through the system unchanged it can not of course induce the guaiacol effects and the sooner this is recognized by the profession the fewer will be the disappointments bound to occur after its employment.

The substance we have examined, guaiamol,* is guaiacol ammonium sulphate, $C_6H_3\begin{cases}OH\\OCH_3\\SO_3NH_4\end{cases}$ It differs from thiocol only in having a NH_4 group in place of the K atom, a difference which would in nowise affect the action of the body. It exists in crystalline form, is freely soluble in water and is devoid of irritant properties.

We have determined first whether the substance is antiseptic and whether it is split up by the pancreatic ferments, and secondly, whether it is broken up in the body after absorption, with the liberation of guaiacol. The second point would be shown by changes in the sulphur compounds in the urine.

As we were completing our experiments a paper by Knapp and Suter[6] appeared in which experiments on thiocol were described. The experiments were carried out in a manner very similar to ours, and the conclusions reached were that thiocol is not an antiseptic, is not broken up in the body, and hence is of no value as a substitute for guaiacol.

In testing the antiseptic value of guaiamol, finely ground pancreas was placed in a flask, covered with a 10 per cent. guaiacol solution, and the mixture placed in an incubator at 37° C. A control experiment was carried on at the same time, a one per cent. solution of guaiacol being used in place of the 10 per cent. guaiamol solution. The two flasks were kept in the incubator for two days. At the end of that time the contents of the guaiacol or control flask were perfectly sweet, with no trace of decomposition. The contents of the guaiamol flask, on the other hand, had undergone decided putrefaction. Tests for free guaiacol in this flask were negative. Guaiamol is not an antiseptic then, nor is it split up by the pancreatic ferments.

In determining whether or not guaiamol is broken up in the body after absorption, the experiment was carried out on a medium-sized bitch in the following manner. The experiment lasted ten days and was divided into three periods: One a control period of four days, followed by four days of guaiamol treatment, during which the animal received daily 3 grams guaiamol subtaneously and a final period of two days after guaiamol medication had been stopped. The dog was placed on a fixed diet throughout the experiment, receiving each day 15 grams dry casein. 100 grams crackers, and 30 grams lard. Water was given *ad libitum*. The daily period ran from 9 A.M to 9 A.M., at which time the animal was catheterized and the bladder carefully washed. The urine collected during the twenty-four hours was mixed with the bladder washings and the volume made up to 1,000 c.c. In each day's urine were estimated the total sulphur, inorganic sulphates and ethereal sulphates, these being calculated in terms of SO_3. The method of determination is very briefly as follows: For the total sulphur, 75 c.c. of the diluted urine were evaporated to dryness in a silver crucible over the water bath, and the residue fused with NaOH and KNO_3. SO_3 determinations were made in the ordinary way by precipitating with $BaCl_2$ and weighing the $BaSO_4$. For the inorganic sulphates 100 c.c. of the diluted urine were precipitated with $BaCl_2$ and the $BaSO_4$ weighed. For the ethereal sulphates 100 c.c. of diluted urine, after removal of the inorganic sulphates, were boiled with HCl and then treated with $BaCl_2$. The determinations were all made in duplicate.

The difference between the total sulphur and the sum of the inorganic and etheral sulphates, all expressed in terms of SO_3, indicates the "neutral" sulphur, together with oxidized sulphur of a type which does not allow of being split off as H_2SO_4 on boiling with hydrochloric acid. In the ethereal sulphates the sulphur is attached to a carbon atom through an oxygen atom, whereas in guaiamol the sulphur atom is linked directly to a carbon. Hydrochloric acid splits off the sulphur in the former condition, but not when it exists in the latter form. Unchanged guaiamol will therefore appear in the neutral sulphur fraction of the urine. If it is split in the organism, with a liberation of guaiacol, the ethereal sulphate fraction will undergo an increase, corresponding to about 50 per cent. of the amount of liberated guaiacol.

The protocol of the experiment is as follows:

Day.	Volume of urine in c.c.	Total Sulphur.	Inorganic Sulphates.	Ethereal Sulphates.	Neutral Sulphur.		
1	235	0.600	0.324	0.021	0.255		
2	195	0.513	0.290	0.022	0.201		
3	310	0.620	0.320	0.016	0.284		
4	240	0.666	0.400	0.023	0.243	3 grams	guaiamol.
5	230	1.800	0.422	0.030	1.348	"	"
6	300	1.705	0.401	0.032	1.272	"	"
7	210	1.589	0.404	0.039	1.146	"	"
8	215	1.548	0.432	0.038	1.078		
9	260	0.711	0.391	0.035	0.285		
10	240	0.537	0.332	0.026	0.179		

AVERAGES.

Fore period	0.600	0.333	0.021	0.241
Guaiamol period.....	1.660	0.415	0.035	1.211
After period	0.624	0.361	0.030	0.232

As the figures indicate, the neutral sulphur fraction was largely increased on the days during which guaiamol was administered. This increase, calculated in terms of SO_3, and taking daily averages, was equivalent to 0.970 grams SO_3. Since the 3 grams guaiamol taken contained 1.085 grams SO_3 the conclusion must be reached that 89.4 per cent. of the substance was excreted unchanged. The slight rise in the daily amount of ethereal sulphate indicates that a certain quantity of guaiamol was decom-

* Guaiamol, which we have taken as a type of sulphonated guaiacol compound, was kindly furnished us by Schieffelin & Co. In justice to this firm it may be stated that this drug has never been placed on the market.

6 Knapp and Suter, Arch. f. exp. Path. und Pharmakol., Bd. 50, 1903.

posed in the body, since guaiacol, as above stated, is excreted in the form of a combined sulphate. The daily average increase in the ethereal sulphates amounts to only 0.014 grams SO_3, which is equivalent to 0.0387 grams guaiacol or only 1.29 per cent. of the quantity ingested.

There is to be noted in the table a marked decrease in the daily excretion of neutral sulphur after the first guaianiol day, a decrease which runs parallel with the total sulphur output. Since the ethereal sulphates do not show a corresponding increase, the explanation cannot be found in the assumption that the organism is gradually taking on the power to decompose guaiamol. The decrease must be ascribed to a lessened output of those compounds usually classed as neutral sulphur, namely ethyl sulphur, oxyproteic acids, cystin, taurin, etc., but why this occurs we are at a loss to say.

Our results are, therefore, in complete accord with those of Knapp and Suter as concerns thiocol. By the most liberal estimate 10 per cent., but most probably only one to two per cent. of the guaiamol ingested undergoes decomposition in the organism after absorption.

The conclusions reached are as follows: (1) Guaiamol is not an antiseptic; (2) it is not broken up by the pancreatic juice; (3) after absorption it is decomposed to such a slight extent that no action due to guaiacol liberated could occur.

These results serve to emphasize the fact that all attempts to increase the solubility of drugs by sulphonation are valueless from a therapeutic standpoint.

ADDRESSES.

THE MEN WE LOST.[1]

BY S. J. MELTZER, M.D.,
OF NEW YORK.

THE remarks, which custom requires of me to make at this occasion, will be confined, as at last year's meeting, to matters pertaining to the affairs of the Association. Last year your president advocated a widening of the scope of the Association, and recommended the appointment of a committee which should formulate appropriate changes in the constitution. The recommendation being approved by a vote of the members, the president named seven members to serve on that committee which was termed Committee on Reorganization. After due deliberation and consultation with the members of the council, the committee recommends changes in the constitution which in the first place would enable the association to include in its membership scientific investigators as well as surgeons who do special work in gastro-enterology; and in the second place would make an irreproachable moral standing an indispensable requisite for acquiring and retaining membership in this Association. The council recommends the adoption of these changes. The report of the committee will be read to you at the executive meeting. According to the constitution, these changes could not be voted upon until next year. However, a part of the desired aims could be already realized the coming year if the president should be empowered to continue the present Committee on Reorganization for the purpose of studying the men who appear to be very desirable as members of our Association and to invite them to join our ranks. The present occupant of the chair would be very gratified if he could thus contribute to the elevation of the scope and standard of this Association.

In the address of last year I was happy to be able to point out that we never met yet with the flag at half mast. We still have reason to be thankful to the fates for the integrity of the ranks of our active members. I have, however, to record with profound regret that in the course of the past year one of our foreign members, a master mind in our science, was taken from us. I refer to Franz Riegel, who, through some inexplicable error, has been classed only among the corresponding members of this Association. Furthermore, in looking over the list of our foreign members, which originally comprised seven celebrated names, I found that nearly one-half of them have already been taken from us by death. Besides Riegel, fate has taken from us Adolph Kussmaul and Samuel Fenwick. There is no record that at the meeting of 1903 due notice was taken of these bereavements which occurred in 1902. It was an oversight which it is not now too late to correct. While it is within the scope of my duties to speak to-day of the life of Franz Riegel, I am sure the Association will grant me the privilege to speak also of the lives and works of the other great men who honored us during their life by accepting the membership of our Association.

Adolf Kussmaul was the first of our losses. He died May 28, 1902, at the age of eighty, of heart failure, half an hour after he experienced some stenocardiac symptoms for the first time. He was born in Graben, near Carlsruhe, Germany, as the son of a country practitioner from whom he inherited the faculties of a naturalist and the love for medicine. After completing his medical studies in Heidelberg and taking some post-graduate studies in Prague and Vienna, he served for a short time as military surgeon in the Baden army and then settled in Kadern, a small town in the picturesque region of the Black Forest, where he carried on a successful practice for four years until he became incapacitated for many months by an attack of paraplegia of obscure origin. After recovering from this disease he decided to begin life anew and to prepare himself for an academic career. With his meager savings as a base he pursued the study of the scientific branches of medicine in Würzburg. In 1856 he was admitted to the University of

[1] President's Address, delivered at the opening of the eighth annual meeting of the American Gastro-Enterological Association, held at the Academy of Medicine, New York, April 24 and 25, 1905.

Heidelberg as Privat-Docent and in the following year he was appointed professor extraordinarius. In 1859 he was called to the regular chair of medicine in Erlangen; in 1864 he went to the University of Freiburg and in 1876 he was called to the University of Strassburg. In 1888 he retired from his academic positions and spent the remainder of his life in his beloved Heidelberg.

Kussmaul was undoubtedly one of the greatest clinicans, one of the most accomplished physicians of his age. He was a harmonious personality; in him the great faculties of the naturalist and the physician were coupled with kindness and simplicity of heart, and in him were united the common sense of the practical man with a fine poetical spirit flavored with a delicious humor. He was admired and loved. His scientific contributions are too numerous to be mentioned at length here. They extend into nearly every department of medicine. Many of his contributions exerted a deep influence upon the science and practice of medicine, and some became common property to such an extent that their originator is already forgotten. Some of his writings are real classics. I mention only the essay on the Psychology of the Newborn or the important essay on the Disorders of Speech. He was a pioneer in many domains of medicine. It is hardly known that he was the first one to describe osteomyelitis, to attempt the construction of an ophthalmoscope, or to develop gastro- and esophagoscopy, to establish the relation between anemia and convulsions; the first one to point out the importance of coryza for the suckling baby, to describe bulbar paralysis, to describe and analyze diabetic coma, to introduce the method of thoracocentesis, the first one to diagnose *intra vitam* embolism of the mesenteric artery and to describe the diagnostic significance of the pulsus paradoxus. There are a good many more important contributions to general medicine which we cannot mention here. But we have yet to speak of his great service to gastro-enterology. He was the first to employ a stomach tube, and by this step he undoubtedly gave the first and most important impulse to the modern development of our knowledge of the diseases of the stomach. His articles on the treatment of the dilatation of the stomach and on the peristaltic unrest of the stomach are classical contributions to our subject. Many important additions to our knowledge have been published by his assistants and pupils under his direct influence and active cooperation. Of those which interest us here I shall mention only the following few: On the presence and absence of hydrochloric acid in gastric juice by Van den Velden; the classical prize essay by Poensgen on the motor activities of the human stomach; on the treatment of the ileus by washing the stomach, by Arnold Cahn; on the acids of the healthy and diseased stomach by Cahn and von Mehring. Kussmaul's last contributions to gastro-enterology were made from his retreat in Heidelberg while already over seventy; they are practical and of permanent value, namely, the treatment of gastric ulcer by large doses of bismuth, and the treatment of chronic constipation by enemata with large quantities of oil.

When already over seventy-five years he wrote his celebrated autobiography, Juvenile Recollections of an Old Practitioner, an inspiring, fascinating little book. Old age had not curtailed the usefulness of that great and lovable man. I shall finish with the statement that to my knowledge Kussmaul never attempted to write a textbook.

It might not be unprofitable to speak of Kussmaul as a practitioner and clinician. All his assistants and pupils could not praise enough his kindness and devotion to his patients. While he was an enthusiastic investigator, he never permitted the study of a case in a manner which could bring harm or discomfort to the patient. The patient was always first and science second, a high principle which should be burned into the minds of our generation of overproductive specialists. Kussmaul told his students he wished them to pass through a serious disease, it would help them to become good physicians, they would then understand what care, kindness and tenderness meant to a suffering patient. Kussmaul himself learned this lesson during his own sickness and did not forget it for half a century. He insisted that his students should learn the particulars of nursing, the making of a bed, the handling of a patient, the preparation of his food, etc. Above all he laid great stress upon the moral and mental influence of the physician upon his patient. He believed in making the patient at least hopeful and cheerful even if he could not be made well. Kussmaul was a great and good physician even if he did not believe in the more godly though less humane doctrine of Truth in Medicine. May the life of this great man be an inspiring example to the younger generation in this country.

Samuel Fenwick died December 11, 1902, at the age of eighty-one years, of heart failure, due to atheroma of the aortic valves. He was born in 1821 in Northumberland, England, of a family which played a conspicuous part in that country for seven centuries. He was compelled to study medicine on account of pecuniary losses which his father had sustained. At the age of fourteen he was apprenticed to the Royal Infirmary of Newcastle-on-Tyne, from which, after seven years, he graduated as M.R.C.S., England. In 1846 he obtained the title of M.D. from the University of St. Andrews. While he was still in the twenties he undertook original researches upon the process of digestion and absorption in lower animals, wrote a book on the chronic diseases of the throat and was appointed lecturer on pathological anatomy at the Durham School of Medicine. He moved later to Newcastle where he acquired a consulting practice said to

have extended over the whole of the north of England. In 1859 he was made honorary M.D. by the School of Medicine of Durham. In 1862 he moved to London where he acquired an extensive consulting practice which he carried on uninterruptedly to the very last days of his life. His private practice seems to have been confined essentially to the diseases of the stomach. In London Hospital, however, where he went through all grades until he became senior physician, he taught many branches of medicine, beginning with physiology. Fenwick was a prolific writer on many subjects. He wrote several text-books which passed through a number of editions. In the later years of his life, his writings were mostly on subjects of gastric diseases. He was probably among the first to write a book on the diseases of the stomach. It was in 1865 and the title reads: "Morbid States of the Stomach and Duodenum." The ninth edition of that book was revised by him fourteen days before his death. He was a man of dignified reserve. He led a retired home life, which was due, it is stated, to a very delicate stomach, a condition which might have been also the reason for his paying special attention to the morbid conditions of that organ.

Franz Riegel died August 26, 1904, at the age of sixty-one, of a malignant neoplasm of the lungs. He was born February 9, 1843, at Brückenau, and was the son of a physician. He studied medicine at Würzburg and after graduating there with highest honors, took a post-graduate course in Vienna under Oppolzer and Stricker. Returning to Würzburg he became assistant first to Bamberger and later to Gerhardt, both celebrated clinicians of their time. In 1871 Riegel became privat-docent at the university, where he lectured on experimental pathology. In 1874 he was appointed director of the City Hospital in Köln, whence he was called (1879) to the University of Giessen to the chair of medicine, which was first filled before him by such celebrated clinicians as Niemeyer and Seitz. The twenty-fifth anniversary of this appointment was celebrated last May by his many pupils, friends and admirers, his assistants and pupils dedicating to him a valuable and extensive Festschrift. He then commenced to show the distressing symptoms of his vicious malady, which, after a few months of suffering, took him away from us in the midst of his active, useful life.

Riegel was a very earnest character, a savant who knew no leisure and no amusement, but hard work and earnest studies which to the last days of his fruitful life he devoted to the science and practice of medicine. His publications are numerous and all very valuable. Differing from most of the distinguished clinicians of his time for whom pathological anatomy was the essential factor of their scientific productivity, all of Riegel's works bear a physiological stamp, his interest centered in functional problems of life, and many of his clinical observations were supplemented by thorough experimental studies. His biographers say that the foundation for this direction of mental activity was laid in Vienna by his contact with Stricker. While I do not doubt that Stricker exercised a certain influence upon the future scientific direction of Riegel, I personally believe that the inclination for the study of functional rather than morphological problems is an inherent one with the individual. It was, so to say, congenital with Riegel. The subject of his thesis, which was written before he met Stricker, was already of a physiological character. It dealt with the respiratory movements in health and disease. Later he returned again and again to the studies of the respiratory organs, to stethoscopy, to the nature of asthma and its treatment, etc. What a fate to die of a malignant disease of an organ to the study of which he had paid so much attention! Undoubtedly he must have made his own diagnosis. Other extensive studies were devoted to the vasomotor influences, to the arterial pulse, to the venous pulse, to the contractions of the heart, to the conditions of the heart and blood pressure in nephritis, to the effects of jaborandi, caffeine, atropine and other drugs. A good part of his work, at least during the last two decades of his life, was devoted to the diseases of the stomach in which field he undoubtedly occupied the first rank. It would nearly be writing a detailed history of the present state of knowledge of gastric disease, were I to attempt to count up the work which Riegel and his able assistants have done in this field. By the present almost exclusive use of a test breakfast, it is practically forgotten that the importance of this method lies in the test meal and that this was first used and introduced by Riegel in 1879. The last work coming from the pen of Riegel was devoted to a discussion of the distinction between hyperacidity and hypersecretion. It is of psychological moment to know that Riegel himself often suffered from gastralgia accompanied by hypersecretion.

By the undertaking of Nothnagel to publish classical monographs on all chapters of medicine by leading clinicians, Riegel was induced to treat of the diseases of the stomach; it resulted in the production of a masterpiece. In the last months of his life he was engaged in the preparation of a second edition of this classical book. It was one of his great worries that he was unable to finish the revision of it. Let us hope that one of his many able assistants will be able to complete it in the spirit of the dead master.

Contribution to the Question of Thymus Hypertrophy.—The possibility of wrongly mistaking other conditions for hypertrophy of the thymus, merely upon the basis of the results of percussion alone, is firmly emphasized by G. TADA (*Jahrbuch f. Kinderheil.* Jan. 2, 1905). Internal and parasternal dulness, particularly to the left of the sternum, if unaccompanied by any definite symptoms, does not warrant the diagnosis of enlargement of the thymus, but should rather point to tuberculosis of the mediastinal lymph nodes.

THE FUTURE OF THE LARYNGOSCOPE AND THE STUDY OF LARYNGOLOGY.[1]

BY JOHN NOLAND MACKENZIE, M.D.,
OF BALTIMORE, MD.;
CLINICAL PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE JOHNS HOPKINS UNIVERSITY, AND LARYNGOLOGIST TO THE JOHNS HOPKINS HOSPITAL.

WE meet to-night to celebrate the making of an epoch. With simple, yet imposing ceremonial, the laryngologists of the world are to-day doing the man who made their handicraft possible deserved and conspicuous honor. Among other testimonials of their respectful and distinguished consideration and high regard, they have hung on the walls of the Laryngological Society of London—the city of his adoption—his life-like portrait, from the brush of a great artist, as a token of their admiration and affection—in loving and enduring memorial.

Surrounded by his British colleagues and by representatives from other lands, in the quiet dignity befitting such an occasion, he is to receive this graceful tribute to his worth and is to be brought face to face with the crowning glory of an hundred years.

He has seen his invention buried in an almost unfrequented grave—he has witnessed its resurrection, its desperate struggle for even recognition, its hard-fought battle for supremacy. And he has seen, too, the stirring events which have led up to its final triumph pass him by in orderly and stately procession; and standing on the threshold of another century of life, it has been vouchsafed to him to see through the vista of the years to come, the realization of his fondest dreams.

In this hour, when in the chief cities of the two great English-speaking empires, the laryngology of the New World unites with the laryngology of the Old to do honor to Manuel Garcia, it has occurred to me, in replying to the courteous and flattering invitation of the President and members of this body to be with you this evening, that it might not be inappropriate to ask what the future has in store for the application of the discovery which has linked his name so inseparably to the history of our art. It seems, too, that the occasion is a proper one to enter an earnest plea for the more perfect study of laryngology as a part of the general scheme of medical education.

The story of the past of the laryngoscope has been so often and, especially on this occasion, so eloquently told, that he would indeed be rash who ventured any variation on this theme. What most concerns us now is the question what is to be the final outcome of the early labors of him whose centenary we signalize with jubilee and memorial to-day? What will be their ultimate reward?

The future of the laryngoscope can, I think, be best discerned by following the history and development of the undergraduate study of laryngology, for it is chiefly along this line that the art of laryngoscopy is destined to come into common use. The general introduction of laryngology as a compulsory part of the curriculum of the medical college is the coming event which has already cast its shadow before.

The study of laryngology has been greatly neglected, until very recent years, in the medical schools of this country and Europe. It has either been omitted from the schedule of studies entirely or, in many colleges, at least, it is taught in a superficial or perfunctory sort of way that inspires neither faith in the instructor nor interest in the student.

Although the catalogue often tells in glowing terms of a course in laryngology, such a course will be found in practice to be like the "Co." in "A Tetterby & Co." a mere poetic abstraction, altogether baseless and impersonal. In very few schools has it been taken at all seriously, while it was not until the year 1893, and then in only one institution, that it was made an obligatory study and a requisite for the degree of Doctor of Medicine. Nor has the position assigned to laryngology in the university been at all commensurate with its importance, and yet of all the pure specialties, that is to say, those branches requiring special technic and special instruments and methods of precision, it is the most generally useful to the diagnostician and general practitioner. The time has gone by when it is necessary to press the claim of laryngology to recognition of the highest rank. We no longer apologize—we demand. There was a time, now very remote, when laryngology meant little more than the art of laryngoscopy, and it was often prostituted to inferior use. It is no longer a simple method of examination and demonstration, but an enduring, vital force in medical progress, which lives and breathes and has its being within the very heart of inner medicine itself. It is no longer the Canaan of the quack, but a fair land of promise for the highest order of research. It should therefore hold high place in the curriculum of the college and university. It should have a separate, thoroughly equipped department and a full professorship. While I do not wish to overestimate the relative value of laryngology in a scheme of medical education, and while I am fully conscious of the present congested condition of the schedule and the future necessity of a large number of elective studies, I am of the opinion that, in view of its very great importance, it should remain as it is in the curriculum of the Johns Hopkins University—an obligatory study. If laryngology and ophthalmology should ever disappear from the list of compulsory studies, they should be the very last to go. Their exile from a curriculum in which they have been once established would be, not an act of progress, but of retrogression.

The time is fast approaching when a knowledge of the use of the laryngoscope will be as

[1] Address before the New York Academy of Medicine, March 17, 1905, at a meeting to commemorate the one hundredth birthday of Manuel Garcia

necessary to the equipment of the advanced physician as is now a knowledge of the physical examination of the chest. Not only the schools, but the public will demand it. It is impossible to exaggerate its importance to the medical and surgical diagnostician in the early detection of disease, not only in the respiratory organs themselves, but, of equal, if not superior importance, in neighboring and remote organs of the body. Long in advance of the appearance of classical signs and symptoms of disease in other organs it often points the way to grave disorder.

Time was, not very long ago, when physical diagnosis of the chest was not required of the medical undergraduate and when the special knowledge of the art was supposed to be, and practically was, confined to the few. Now every practitioner of medicine knows, or thinks he knows, it all. The laryngoscope will go, indeed is already going, the way of the stethoscope and become the common property of the general practitioner of medicine. It will be an absolute necessity in that great specialty, which next to surgery, is the highest of them all—internal medicine. The time is quickly coming when the art of laryngology will be linked to general medicine as the art of physical diagnosis of the chest has become its inseparable associate. How it must rejoice the heart of the old man across the seas to feel that a knowledge of the working of his invention, which together with its first results was consigned to obloquy and oblivion in the Transactions of the Royal Society, is, in some quarters at least, necessary to the acquisition of the medical diploma and is destined in time to come into universal use among medical men.

The great advance made by laryngology in recent years, the rapidly growing necessity of a knowledge of its special province in the elucidation of obscure conditions in other and remote organs of the body, the popularity of its study and the accordingly rapidly increasing number and far-reaching geographical distribution of its votaries, are only some of the causes that have led to the increasing general knowledge of the art of laryngoscopy. But perhaps the most significant and convincing phase of the question is to be found in the slow but certain progress of laryngology to a commanding place in undergraduate instruction. It is in the study of laryngology in the undergraduate curriculum that will be found the compelling force and resistless undercurrent that is to carry the laryngoscope to its permanent abiding place beside the stethoscope and other absolutely necessary instruments of precision in the outfit of the medical diagnostician.

The proper time to lay the foundation for the educated laryngologist is in early life, in his early studies, in his undergraduate days; for it is at this period of his medical training that he is in the best position to acquire that fundamental knowledge and, what is of more importance, that breadth of mind which is so essential to his future development. At this receptive period of the development of his mind he can best recognize the limitations of each special branch of medicine and can best be taught to generalize profoundly not in one but in all departments of medical thought. It is at this stage of his career that it is impossible for him to cut loose from the other departments of medicine. The growth of his special studies goes on *pari passu* with his advance in other lines of work and he is brought in daily contact with disease in other organs of the body. He learns at the outset that no department of medicine is isolated and independent, but that they are all mutually dependent and coordinate. And if he is made of the proper stuff, this fundamental lesson and illuminating first impression will follow him in his special work in after-life as an inspiration and a guiding star.

Let us now turn to the development of the study of laryngology in our medical schools and in doing so you will forgive me if for a moment my remarks become personal and reminiscent. I may perhaps best illustrate the different phases of its development by giving a chapter from my own experience.

Twenty-four years ago, when I was on the working staff of the then largest laryngological clinic in London, the Hospital in Golden Square, there was no place in that vast metropolis where the student could get systematic instruction in special work. None of the colleges or hospitals gave lectures on laryngology—nowhere was it requisite for the degree. All strangers in London interested in the specialty, came to Golden Square, attracted there by the personality of Morell Mackenzie, then at the zenith of his popularity and power. With all the enormous material at our command, there was practically no instruction given, except in the way of hasty demonstration of cases; and if the student or visitor learned anything, it was through close personal observation on his part and not through any gigantic effort to impart knowledge on the part of the medical staff. With one or two exceptions the latter directed their attention almost solely to the larynx and thyroid gland, and the nasal passages were only examined when in quest of a polypus or when the attention was irresistibly attracted to these organs by the horrible stench of an ozena. The nasal cavities were practically neglected and the only apparatus in the hospital for the treatment of their diseases consisted of a pair of forceps for the removal of nasal polypi, and a handball atomizer with a detergent solution for the treatment of ozena or any other miscellaneous disease of the nose that might irresistibly obtrude itself upon the recognition of the medical staff. When later I studied on the Continent, I found a like condition of affairs. In no school was laryngology taught to undergraduates, and the only means of acquiring special knowledge of the subject were the imperfect courses on diseases of the larynx, given by the professors and their assistants. There

was no special course in rhinology, which subject, as in England, was left entirely alone. I returned to my own country to find the same neglect of the study of laryngology that I had found in England and on the Continent.

In 1887 I was called to the chair of laryngology and rhinology in one of the oldest medical schools in America. The annual catalogue and circular told in flamboyant terms of a course on laryngology which at once set the mind to wondering how it would be possible for a student to escape from the institution without absorbing all that was coming and all that had gone before in that imperial domain. On my induction into office, I cast about me for the paraphernalia which should accompany my lofty position. I found in a dark closet or rather hole which led under the seats in the amphitheater where the lectures and clinics were given, a dilapidated lamp whose structure and general appearance of antiquity suggested the possibility that it might have been originally trimmed by some spirit in the age of fable, a broken laryngeal mirror, from whose back the quicksilver had long since departed and a cardboard diagram, colored blood red, like an eczema, which was supposed to represent the laryngeal image, but looked more like the Baltimore fire. These crude implements of the laryngoscopic art I found—and a tradition. According to this tradition my predecessor in office was accustomed to meet his class at the opening of each session, and, after a few introductory remarks, disappeared with a patient into the closet under the seats and closed its door. There was a period of breathless silence and intense expectation on the part of the students, during which time all manner of strange noises were heard in the darkness beneath them. These finally ceased, and the professor reappeared, his face radiant with satisfaction, and advancing toward the class, with the laryngeal mirror held aloft, triumphantly exclaimed: "Gentleman, I have seen the vocal cords!" According to the same tradition, that was all the laryngology the class got during the session.

The quarters assigned to me in the dispensary, where the patients were examined, consisted of a little compartment or "box" from which all sunlight and fresh air were carefully excluded, and in the foul atmosphere of which it is probable that two of my assistants subsequently contracted tuberculosis. It was thus thoroughly equipped and under such cheerful conditions that, without either moral or financial support on the part of the executive branch of the institution, I began the task of teaching practical laryngology to undergraduate students. Fortunately, I had good assistants, with whose aid I soon built up an excellent clinic, so that we were enabled to give the men during the session demonstrations of most of the diseases of the upper air-tract and all the common operations on the nose and throat. I gave the lectures and clinics, and my assistants superintended the instruction of the students in the dispensary. Although attendance in the department of laryngology was not compulsory, and although no examinatoin was ever held in this branch, the course was largely attended and many became so much interested in the subject that they subsequently took it up as a specialty.

This was practically the condition of affairs in the undergraduate study of laryngology, when in 1889, the Johns Hopkins Hospital threw open its doors, and when, several years later (1893), the medical school in connection with it and the university was formally opened. The Johns Hopkins University deserves the credit of being the first institution of learning, either in this country or beyond the seas, to give to laryngology the prominence which its place in medical education demands. It was the first to make it an obligatory study in the curriculum, and to make an examination in this branch a requirement for the degree of Doctor of Medicine. This was one step, and in consideration of the former neglect of the subject, a prodigious one, to place laryngology where it properly belongs and to give it the position and prestige to which it is justly entitled. It marks, therefore, an important era in the evolution of the undergraduate study of laryngology. As a matter of historical interest, and in response to many inquiries on the subject from teachers of laryngology in various parts of the country (which simply echo the forward march of progress in this department that is being sounded in other serious colleges throughout the land), although I have done so before, I think I may be pardoned if I again ask attention to the method of teaching the specialty which has been adopted in this institution. I shall content myself with simply giving a mere outline of the work, and shall not enter into matters of detail.

The time required for the degree of Doctor of Medicine is four years, of nine months each. The requirements for entrance to the medical school are rigid, only those being admitted who give evidence of having had a liberal education as indicated by a collegiate degree in arts or science, including an acquaintance with Latin, a reading knowledge of French and German, and adequate training in physics, chemistry and biology. The first two years are devoted mainly to practical work of all kinds in the laboratories of anatomy, physiology, physiological chemistry, pharmacology and toxicology, pathology and bacteriology. During the last two years much of the student's time is spent in practical work in the wards, laboratories and dispensary. It is not until the fourth year that the class enters the special departments. It is my intention to give a course on laryngology in the third year, so that when the student enters his graduating or fourth year course, he may be at least familiar with the use of the mirror. I mention these facts simply to show that, when the student reaches me, he is quite thoroughly trained, not only in the use of

his brain, but also in the use of his hands. By constant practical work for three years, he has acquired an amount of manual dexterity which enables him to master the art of laryngoscopy with relative ease.

The graduating class is divided into sections—each section (of the fourth-year class) attends for one and one-half hours daily during two months, the laryngological and rhinological department, where they receive practical instruction from my assistants and myself. After preliminary drilling in the use of the laryngoscope and other technical procedures, and in diagnosis, the student assumes the work of clinical assistant. He is given pathological material for examination and diagnosis, and is encouraged to report cases and read papers before the Hospital Medical Society, to look up the literature of interesting subjects connected with laryngology, to observe for himself and, if he has time, to do original work. He is taught to investigate and to inquire, and I may say just here that it often requires a very high order of human ingenuity to construct an evasive answer to some of the conundrums with which I am frequently assailed. He takes his first lesson on the human subject—gets his first impression from Nature. I formerly used models; but some one stole them and I am glad they are gone.

By the above method, the teacher comes into direct personal contact with each member of the class, and is enabled to measure the mental status and personal equation of the individual. In no other way can laryngology be properly taught. It is hard work, but it pays in the results which are accomplished. Laryngology can not be taught by text-book or lecture. It must be taught over the shoulder of the instructor, and on the part of the student, must be acquired by direct contact with, and personal observation on, the living subject.

Each student, by this method, becomes an individual responsibility—a special care. And just here let me observe that the day of operating before crowded benches is no more. The amphitheatre with its old-fashioned surgical clinic will soon become an anachronism. Tier after tier of seats in an operating room is simply a waste of space which could be utilized in a far more profitable manner. No more play to the gallery—no more spectacular performance! Of all the special studies, laryngology is the most difficult and troublesome to teach. It involves hard, painstaking work and patience, not only on the part of the teacher, but also on the part of the student. Each student, as I have said before, is practically a special pupil and must be individually instructed; and to that end the chief of the department should have a corps of trained assistants whose work he may complement and supervise.

While the didactic lecture is fast becoming an anachronism, I do not believe that the day of its usefulness is completely gone. I give a systematic course of weekly lectures to the entire class, which are supplemented by pathological and clinical demonstrations, on the anatomy, physiology and commoner diseases of the upper air-passages and their relations to morbid processes in other parts of the body. In this course especial attention is paid to diagnosis. The object of these lectures is two-fold; (1) to give in a concentrated form and in the shortest possible time information which could not be acquired except by great additional labor on the part of the student, and (2) to avoid endless repetition in the section room. One year I abandoned the didactic lectures altogether and gave up the time to practical work alone; but the change was not satisfactory for many reasons and I was obliged, therefore, to return to this method of instruction.

Among the many questions that are asked me is the justly serious one concerning examinations. The question of the value of examinations is a very important one and one which is destined soon to be pressed to final settlement. While I cannot go as far as my gifted friend and colleague, Professor Mall, who is of the opinion that it would be well to separate them from the course of instruction entirely, I must confess that I am very much in sympathy with him in the main points of his contention. But until a more rational and exact method of accomplishing the same results be devised, I am afraid the examination must remain as a necessary evil. It is often a farce. One of the best examination papers I ever received was from a student who, on account of serious illness, was compelled to absent himself from the very lectures on which the class was being examined. He had used the notes of a fellow student and came back at me with almost my own words. In the university in which I received my first medical degree, instruction, except in the department of anatomy, which was practically and ably taught, was entirely by didactic lectures. We sat all day in the lecture room taking notes, and spent the entire evening "cramming" them for the next recitation. We never saw a medical case. Once during the session, the professor of surgery brought in the colored janitor, stripped him and bandaged his legs and arms. This was our only course in practical surgery. Those were the good old days when, as Mall says, the students "heard much, saw little and did nothing." When the day of examination arrived I knew my text and note books from cover to cover, and could locate with unerring accuracy any required item of information to the page and to the line. My memory was so saturated with medical lore that it took me some years after I left college to forget it. I was invincible in the examination room, but helpless at the bedside.

The best examination is the observation of the student in his daily work and the resulting estimate of his personal equation. During the first two years I gave an oral examination at the end

of the term, carrying each student over the entire field covered by the lectures, but, as the size of the class increased, this had to be abandoned, and I gave a single written examination of which the following, which was my first, is an example:

1. Give the physiology of the nasal and accessory cavities.

2. General symptoms and diagnostic signs of suppuration in the nasal accessory cavities—diagnosis of pus in the antrum maxillare.

3. Early laryngoscopic diagnosis of tuberculosis and cancer; characteristics of syphilitic, cancerous and tuberculous ulceration in the upper air-passages.

4. Chief causes, symptoms and laryngoscopic signs of double, complete abductor paralysis.

5. Nature and diagnosis of so-called nasal reflex neuroses.

Now, instead of the written examination of the entire class at the end of the session, each group of students is given a thoroughly practical one at the termination of its section work and this examination is final.

Each student who graduates from the school must be familiar with the use of the laryngoscope and be able to diagnosticate typical cases of the commoner diseases of the upper air tract. He is marked as in the other departments and the examination affects his standing in the class and operates for or against his chances for hospital positions after graduation. In other words, for the first time in the history of medical education this branch of study has been taken absolutely seriously.

This, in brief, is a simple outline of the way in which laryngology is taught in the Johns Hopkins Medical School. I am fully aware of the imperfections of the method; but everything must have a beginning, and time and further experience will doubtless make it more perfect. In the classes under my care it has so far been very successful. The net result is that when the student graduates he has made a very fair groundwork on which to base, in the future, if he will, a more elaborate study of the specialty.

One of the most encouraging signs of the times is the largely increased amount of space given to laryngology in some of the leading general hospitals of the world. Not to mention others, this is notably the case in such institutions as the rehabilitated London Hospital and the Massachusetts General Hospital in Boston, where entire suites of rooms are devoted to this special department and where the most excellent work is being done. Princely apartments and imposing apparatus, however, count for nothing in the absence of the proper atmosphere to breathe and the proper spirit to direct. Well-directed effort in serious environment can accomplish wonders even in scant quarters and with poor equipment—without them, both material and opportunity go to utter waste. The special department should be (as it is in the Johns Hopkins University), a part and parcel of the organic whole and indestructible trinity of University, Hospital and Medical School, and this leads me to say that the proper place for a special hospital, particularly if it is to be dedicated to teaching, is in connection with a large general hospital, of which it should be, if possible, an integral part, inseparable from its machinery and moving in sympathy and unison with its other departments. For, apart from the obvious convenience and salvation of time to the student, it fosters a more liberal spirit and diverts him from the groove to which a too narrow specialization often acts as a centripetal force. Under these conditions, the laryngology of the future will best be taught. The student in this way is made to see at every turn the relation of his special study to other special branches and general medicine.

No hospital, general or special, ever completely fulfills its mission until it becomes a center of teaching, a factor in education, a means for the dissemination of knowledge.

The instructor will fall far short of his duty if he does not make the student forever bear in mind that laryngology is an inseparable part of general medicine—that the pathology of nasal and laryngeal diseases is not an isolated pathology: that the appearance of diseases in the upper air-tract is governed by the laws that condition the development and course of disease in general, and that the rational interpretation of these affections presuppose therefore the application of general pathological principles to the peculiar conditions which the anatomical and physiological functions of the structures involve. Above all, he should remember that peculiarity of structure is not anatomical isolation; he should remember the correlation of organ and organ, the sympathy of tissue and tissue which make up the perfect physiological life of man. In looking upon the subject from the high vantage ground of general pathology and laws of health, the student is in a better position to apprehend the rôle which external and internal influences play in the evolution of diseases of the respiratory apparatus, than if he viewed the subject from the level of a narrow specialism or from the standpoint of the mere empiric.

Laryngology should not be studied apart but kept in constant and closest contact with all the other departments of the university. Let there be more fraternity among the different specialties—more cooperation. If special workers in the different departments of medicine would, instead of holding aloof from each other, combine the special knowledge they possess in a common endeavor to elucidate the difficult problems which daily confront them, the hostile cry of ignorant criticism, which is so often directed against them, would be forever silenced by their discoveries for the common weal.

What effect will the increasing general knowledge of laryngological technic have upon the future practice of the specialty?

In some ways, and for obvious reasons, it will mean the passing of many. It will mean, let us hope, the relegation to the rear of that unfortunately numerically large element in our midst whose chief claim to special knowledge resides in the possession of the necessary apparatus which goes to make up the armamentarium of a worker in this field and whose highest conception of their calling is the "method of the nickel in the slot." But in other ways, as for example, by exacting more rigid requirements in laryngological education and by elevating it to a higher plane, it will doubtless redound to its everlasting good.

We shall soon reach a point where we shall be at the parting of the ways. On the one hand stretches out the broad highway that is easily trod by the superficial, the careless, the ignorant. On the other hand the narrow pathway, beset with obstacles which can only be conquered by him who, after a broad and liberal general medical education, bends his energies to constructive work and sets his face in the direction of high ideals.

The fate and fortune of laryngology is in the hands of the coming generation of teachers and students and it will depend upon their character whether the specialty will endure as a vital illuminating factor in medical progress, or whether, in the contest that is sure to come, it will go down before the might of the forces that are arrayed against it. If combat comes, let laryngology not idly wait to be obliterated or absorbed, but let her invade fresh territory of medical thought and with conquering arms extend the boundaries of her realm.

The laryngologist of the future will, as never before, be forced from intellectual solitude and isolation into the arena of the world of outside interest and activity. His voice will no longer cry aloud in the loneliness of special seclusion, but will be heard ringing through every avenue and by-way of the City of Medical Learning and resounding in its forum of debate.

For my own part, I have the utmost confidence in the future. There will be no retrogression, and in the not distant day when the art of laryngoscopy shall be looked upon, not as an accomplishment, but as a necessity, the fittest will survive. The time will come when the scientific laryngologist will be absolutely indispensable not only in the field of practical medicine, but in the realm of original research; and in the future evolution of our special knowledge it will come to pass that the waves that have been set in motion by the ripple caused by Garcia's invention will break on every shore of medical thought.

The study of laryngology will reach the full fruition of its hopes and aspirations by becoming the inspiration of a higher effort and a loftier ideal. It will teach the student not to contract but to broaden the horizon of his intellectual activities. It will make him understand that the laryngoscope is not merely a device for exploring certain hidden recesses of the body and for the demonstration of that which is already known; but an agent of positive power in future research,—a means of scientific expansion and exploration of the unknown. Let laryngology walk with becoming humility beside the great pioneer forces of human endeavor, aiding them, it may be at first, in an humble and unostentatious way, but still contributing to their progress through the trackless wilds of the land that is untrodden and unknown. Undaunted, undismayed, let them press forward, side by side, until the wilderness shall blossom as the rose and Nature's wild forest ring with the shout of their exultant discovery. When this ideal shall have been attained and this conception of our art is realized, then will the study of laryngology light the way for the triumphant march of scientific medical achievement, and the laryngoscope will become, more than ever before, an instrument of progress and power.

MEDICAL PROGRESS.

MEDICINE.

Chylous Ascites.—JAMES F. BELL (*Am. Med.*, May, 27, 1905) reports a case, in a man, age fifty-seven years, in which the amount of fluid withdrawn from October 1 to December 17 aggregated 106,370 c.c. There was little loss of strength or weight, the patient, at the last paracentesis, weighing but five pounds less than his normal average. The history would suggest a rupture of a large lymph duct, the thoracic duct, the receptaculum chyli, or a chylous cyst of the mesentery which has continued to discharge into the peritoneal cavity. The cause of the rupture is unaccounted for and no growth or neoplasm can be found in the abdomen. Dr. S. P. Beebe discusses the literature on analysis of chyle and reports the results obtained from examination of the fluid in this case.

Heroin Habit.—C. E. ATWOOD (*Med. Rec.*, June 3, 1905) notes the variety of cases of heroin addiction and reports one occurring in his practice. The patient was a married woman of nervous heredity to whom the drug had been given as an anodyne with the assurance that there was no danger of forming a habit. She continued to take the drug after the original indication for its use had disappeared, and when coming under treatment was giving herself four grains hypodermically in divided doses daily. A cure resulted from immediate withdrawal with symptomatic, sustaining, and eliminative treatment. The abstinence symptoms were, however, so severe that in a second case the author would resort rather to gradual withdrawal.

Quinquaud's Sign.—This has been described as almost invariably present in cases of chronic alcoholism, by the Frenchman, Quinquaud, and also by the German, Fürbringer. The phenomenon is elicited as follows: The patient places his spread fingers in the palm of the observer's hand. At first nothing unusual is felt, then there is imparted to the examining hand what appear to a series of faint shocks, as if the bones of the fingers were being knocked against each other and against the hand of the observer. These movements may vary from a gentle rubbing to a well-marked crepitation. The value of this sign as an indication of chronic alcoholism has been disputed by various observers, and HOFFMAN and MARX (*Berl. klin. Woch.*,

May 8, 1905) were therefore led to make a more thorough investigation. For this purpose they examined carefully 1,018 inmates of a German prison, who were divided into three classes according to the amount of alcohol consumed. The authors believe that the sign of great value and ascribe greater worth to it than other previous investigators. The absence of the sign, or its presence to a moderate degree, does not permit any absolute conclusions to be drawn either for or against alcoholism, at least as regards total abstinence or abuse, although the probability in favor of abstinence is as three to two. A marked grade of the phenomenon indicates excessive drinking with a probability of three to one. In looking into any possible relation between the ordinary tremor of the hands and this phenomenon, the authors found that there was apparently no connection between the two, one being found in numerous instances without the other. They believe that it is due to a peculiar muscular movement which produces vibrations of the bones in the long axis of the arm, the usual tremor being produced by a transverse motion. In the former case, individual groups of muscle fibers are involved, while in the latter, the whole muscle is concerned.

Observations Upon Amebas Infecting the Human Intestine, with a Description of Two Special, Entamœba Coli and Entamœba Dysenteriæ.—Charles F. Craig (*Am. Med.*, May 2, June 3, June 10, 1905) says that from his observations the following conclusions are warranted: (1) The intestine of man may be infected with two varieties of amebas, one pathogenic (*Entamœba dysenteriæ*), and the other non-pathogenic (*Entamœba coli*). (2) *Entamœba coli*, the non-pathogenic variety, is found in 65 per cent. of healthy individuals studied, and in 50 per cent. of individuals suffering from diseases other than dysentery, if a saline cathartic has been administered. (3) These organisms can be easily distinguished in both fresh and stained specimens. (4) They differ widely in their method of reproduction, and this is the most important method of distinguishing them. (5) *Entamœba dysenteriæ*, whether fed in milk or injected through the rectum, produces in kittens the typical lesions of amebic dysentery as observed in man. (6) In kittens, *Entamœba coli*, whether fed in milk or injected through the rectum, is absolutely harmless. (7) Neither feeding experiments nor rectal injections of fecal material or the bacteria occurring in such material produces any of the lesions of amebic dysentery, unless *Entamœba dysenteriæ* is present.

Sign of Value in Splenic and Hepatic Disease.—T. Horace Evans (*Am. Med.*, June 10, 1905) describes a method uniting both palpation and percussion. The abdominal walls should be relaxed, the lower extremities slightly flexed on the abdomen, and the leg on the thigh. The patient should open the mouth, breathing lightly through it. The physician gently plunges the fingers of one hand into the abdominal wall at the level of the anterior or lateral costal margin, and rather under the osseous curtain of the same. With the fingers of the other hand he firmly percusses over the supposed site of the organ, spleen or liver to be examined. Very delicate sense in the percussion hand will discover a variation of resistance, according to the state of the underlying organ, for the retaining hand secures the liver or spleen, as the case may be, between itself and the superior structure, the diaphragm. The more valuable result is the sensation derived from the parenchyma striking the retaining fingers, which are pressed into the abdominal wall. By a little experience the peculiar shades of consistency of the spleen or liver will make themselves readily perceptible. Any enlargement accompanied by softening or rigidity should be quickly distinguished. In case of typhoid this method is successful for the early diagnosis of splenic variations.

Pathologic Changes in Appendicitis.—E. MacD. Stanton (*Journal A. M. A.*, June 10), has studied the pathologic changes in the peritoneum in 185 cases of appendicitis, and of the appendix in 188 cases, all occurring in the Albany Hospital during the last six years, the notes and sections of which are on file in the Bender Laboratory. The relations existing between the character of the lesions and the stage of the disease were particularly studied in all. The histologic changes in appendices removed during the first few days of the disease were essentially similar and consisted in a severe diffuse inflammation, accompanied by focal areas of hemorrhage and necrosis. These latter may increase in extent during the first few days and give rise to macroscopic areas of gangrene or they may remain microscopic and be quickly repaired. The various anatomic varieties, gangrenous, perforative and ulcerative are due to the extent and distribution of these necroses. Evidences of repair are seen as early as the third day and the process is distinctly reparative in non-gangrenous cases by the fifth day. Even in cases with macroscopic evidences of gangrene, unless a later acute process is engrafted on the original one, the repair proceses predominate by the sixth or seventh day. Evidence of recurrence was observed in 10 or 15 per cent. of the cases after the first week. Repair is rapid during the second week of the attack; fibroblasts, newformed blood vessels and lymphocytes forming the principal features of the picture. The rapidity of repair depends largely on the amount of damage done and on the presence or absence of a periappendiceal exudate. By the end of the second week in most cases repair is so complete that new connective tissue may be the only evidence of previous inflammation, but in cases with extensive exudates, signs of active organization of the exudate itself are still in evidence. After the second week, except in cases with extensive periappendiceal lesions, the histologic changes are seen chiefly in the more fibrous nature of the new connective tissue which is still recognizable. In cases operated on a month or more after an acute attack, 78 per cent. were cases of chronic interstitial or obliterative appendicitis, frequently accompanied with adhesions. In 6 per cent the appendices were apparently normal, and in 16 per cent. the changes were confined to the mucosa. In no instance were the changes confined to the mucosa in the cases examined during the first ten days of the attack. In this series of cases, purulent fluid was found outside of the appendix in 51 per cent. of the patients operated on from the third to the tenth days. After the tenth day the number of cases with abscesses steadily decreased while the number of those with adhesions and without pus rose correspondingly. This, Stanton thinks, was due to the less extensive peritoneal involvement in most of these late operated cases rather than to resolution by absorption. In a number of cases, however, the massive adhesions indicated the prior existence of extensive periappendiceal exudate. After the third day the exudates on the peritoneal surface contain highly vascular granulation tissue, and he thinks it probable that the high operative mortality between the third and tenth days may be in part due to absorption from the denuded granulating surfaces as well as to the extent of the peritonitis and the bad general condition of the patient.

Contribution to Hemophilia.—F. P. Kinnicutt (*Med Rec.*, June 10, 1905) describes the history of a

hemophiliac whose symptoms began in infancy and persisted with great severity until the time of his death, at the age of sixteen years. Frequent attacks of pain and swelling in the joints, including the smaller articulations, due to hemorrhage, and finally leading up to permanent structural changes, were a prominent feature of the case, and death was brought about by an intra-abdominal hemorrhage. The ancestry could be traced with much minuteness, but no evidence of heredity was found. The general nature of the disease is then discussed with especial reference to the occurrence of joint manifestations, and the pathology of such conditions. The author points out the possibility of confusing arthritis of this nature with that of tuberculous or rheumatoid type, and says that in joint affections bearing a resemblance to tuberculous disease in infancy and childhood, the family history, as well as the personal history, should be studied carefully previous to operative treatment. The tuberculin test in a hemophiliac is not without danger from injury by the needle. The question of treatment is considered at some length, the preference being given to the physiological styptics rather than to such agents as tannic acid, salts of the heavy metals, etc. The author speaks highly of the value of calcium chloride in this connection, and says that the present views of the therapeusis of hemophilia may be summarized as follows: (1) The internal administration of the lime salts, especially of the chloride of calcium, in doses of two grammes (30 grains) twice or thrice daily. Its continued use should be interrupted every two or three days by a period of twenty-four hours. (2) The application of solutions of the same salt, with compression, for accessible surface bleedings. Aqueous solutions of one-half per cent. are efficient. Another convenient mode of employment is in the form of a finely powderd chalk mixed with one-half per cent. solution of the calcium chloride. The less soluble lime salts, such as calcium phosphate, are equally efficient for local application. (3) The use of a combination of one-half per cent. solution of calcium chloride and one-sixth volume of a solution of nucleo-albumin, for local application. The nucleo-albumin can be obtained from aqueous extracts of various cellular tissues—testicle, thymus, thyroid, ovary, etc. If the prepared extracts are not available, a supply may be procured readily by mincing any of these tissues in a weak alkaline solution (1-500 solution carbonate of sodium) and filtering through gauze after a few minutes. (4) The application of a stream of carbonic-acid gas to the bleeding surface, in accessible hemorrhage. Its inhalation, freely mixed with ordinary air or oxygen, in concealed hemorrhage. (5) The use of four per cent. solution of choral hydrate for surface bleeding, and also of adrenalin (1-1,000) with compression.

Large Dose of Quinine in Pneumonia.—F. H. POOLE (*Journal A. M. A.*, June 3) reports that he has recently treated thirteen consecutive cases of pneumonia among Indian school children with large doses of quinine, according to the method advocated by GALBRAITH (*Journal A. M. A.*, January 28, 1905, p. 291) without mortality. The initial symptoms common to all cases were intense frontal headache, epigrastic distress and vomiting, and in eight cases epitaxis also occurred as an initial symptom. Three of the five boys had epistaxis at the onset and all had it repeatedly during the quinine treatment. Of the eight girls five had it as an initial symptom. Two of these had never menstruated, but the menses appeared during the treatment; in the other three they also appeared, though not due, and in spite of the fact that the patients had always previously been regular in this respect. In none of the girls did epistaxis appear after the initial symptoms. Poole asks: was this hemorrhagic tendency a part of the disease and peculiar to this epidemic, or were the epistaxis of the onset due to the infection and the later hemorrhages to the treatment? The minimum single dose of quinine given was fifteen grains, the largest thirty-six grains. These large doses proved a genuine stimulant to the heart and circulation and appeared largely to allay the anxiety of the patient and to secure sleep.

Council on Pharmacy and Chemistry Reports on Acetanilid Mixtures.—The first official publication made by the Council on Pharmacy and Chemistry, appears in the *Journal A. M. A.*, May 27. A sub-committee has purchased in the open market original sealed packages of various proprietary and patent remedies containing acetanilid—some of them represented to be chemical compounds and publishes results of its examination of them as follows: Ammonol: acetanilid, 50; sodium bicarb., 25; ammonium carb., 20. Antikamnia: acetanilid, 68; caffeine, 5; citric acid, 5; sodium bicarb., 20. Koehler's headache powders: acetanilid, 76; caffeine, 22. Orangeine: acetanilid, 43; sodium bicarb., 20; caffeine, 10. Phenalgin: acetanilid, 57; sodium bicarb., 29; ammonium carb., 10. Salacetin: acetanilid, 43; sodium bicarb., 21; sodium salicylate, 20. All of these were mixtures. The *Journal*, commenting on the work, calls attention to the danger involved in the physician's prescribing such a remedy as one of the above without knowing that it contains acetanilid. The report is extremely conservative, and repeated analyses have been made so that no erroneous statement should be published.

PATHOLOGY AND BACTERIOLOGY.

The Bone-Marrow in Disease.—Even in this age of active pathological research, the bone-marrow has rarely received sufficient attention and it is to the credit of B. WOLOWNIK (*Zeitsch. f. klin. Med.*, Vol. 56, Nos. 5 and 6) to have pointed out that very often characteristic pictures are obtained in the various disorders. Thus, in tuberculosis, sepsis, pyemia, heart disease, nephritis and carcinoma, the myelocytic type prevails, while in pneumonia, cirrhosis of the liver and other pathological conditions, the lymphocytes are particularly common. There seems to be a distinct parallelism between the large lymphocytes and the myelocytes, and the polynuclear neutrophiles are usually most numerous with suppuration or ulceration. The largest percentage of eosinophiles occurred with pneumonia and nephritis, and if the eosinophiles were increased in other diseases, a nephritis was usually also present. In tuberculosis and carcinoma, a marked increase of giant-cells and normoblasts was noted and a very low percentage of megaloblasts seemed characteristic for nephritis and a few cases of carcinoma.

Agglutination and Hemolysis Through Staphylococci.—In order to determine if there is any difference in the behavior of staphylococci, C. FRAENKEL and O. BAUMANN (*Münch. med. Woch.*, May 16, 1905) examined a large number of these germs from various sources. Hemolytic action was not shown by all, and some dissolved the red blood cells of rabbit's blood early, others late. The most intense hemolytic action was always manifested by the most pathogenic types. Hemolysis could be checked by antihemolysin, obtained by treating rabbits with gradually increasing doses of staphylolysin. The staphylolysin possesses both a haptophor and a toxophor radical; if kept at a low temperature with some red blood cells, the haptophor radical will unite with the latter without causing a solution

since the toxophor radical acts only at a higher temperature. Staphylococci which did not bring about hemolysis at first, did not acquire this property even when injected into mice. An interesting observation made, was that staphylococci causing hemolysis are not well agglutinated by staphylococci which lack this property. The authors therefore conclude that two varieties of these germs should be recognized: hemolytic, pathogenic and non-hemolytic, saprophytic staphylococci.

Toxic Action of Sublimate.—According to D. Bokorny (*Münch. med. Woch.*, May 16, 1905), algae forms excellent objects to study the toxic action of sublimate, since the earliest changes can well be observed under the microscope. The surprising observation has been made that if a certain amount of algae is added to a solution of sublimate as dilute as 1 to 1,000 million, distinct discoloration of the chlorophyll bands may be seen after eight days, showing that death of tissue has set in. The cause of this is an absorption of sublimate by the tissues, so that eventually a much larger amount is brought into contact with them. By a large series of experiments, it could be determined that 0.5 milligrams of sublimate can poison 100 milligrams of protoplasm.

A New Counting Chamber for Blood.—A new counting chamber, devised by K. Burker (*Münch. med. Woch.*, May 9, 1905) is said to be free from all the defects of the original Thoma-Zeiss chamber. The cover-glass can be made to fit very tightly, since it is adjusted before the chamber is filled. Unequal distribution of the red cells is avoided as the chamber fills instantaneously by capillary attraction. Since the chamber is open on two sides, atmospheric pressure will have no influence, and perfectly accurate counts are possible in high altitudes. The counting is facilitated by a scale to be placed into the ocular of the microscope, while in another form, the chamber itself is ruled into squares.

The New Asiatic Blood Fluke.—Ch. Wardell Stiles (*Am. Med.*, May 20, 1905) calls attention to the fact that the newly described Chinese blood fluke *Schistosoma cattoi 1905*, may be identical with a fluke *Schistosoma japonicum 1904*, described for man and cats in Japan. The new species is characterized by the absence of spinose warts on the male and the absence of spine on the egg, while the African blood fluke *Schistosoma hæmatobium*, has spinosa warts on the male and a terminal or subterminal spine on the egg. Clinically, in cases of infections with the African fluke both visical and rectal symptoms have been reported, but all reported infections with the new Asiatic fluke have thus far been intestinal. Another important clinical point is the possibility that some of the cases of cerebral distomatosis, heretofore attributed only to the lung fluke *Paragonimus westermanii*, may possibly be due to the new Asiatic blood fluke.

The Elective Action of Chloroform on the Liver. Doyon has demonstrated that in certain conditions chloroform produces the following parallel changes: Incoagulability of the blood, a disappearance of fibrinogen from the plasma and lesions of the liver. M. Doyon and J. Billet (*Comptes Rendus*, May 8, 1905) have found that chloroform has an elective action on the liver, with the exclusion of all other organs, with the exception of the kidneys. Introduced into the stomach of the dog, chloroform causes the following changes in the liver: Abundant hemorrhages, an enormous accumulation of polynuclear leucocytes in the interlobular spaces, degeneration of the hepatic cells, particularly a general marked fatty degeneration. The kidneys show the lesions of acute nephritis.

Action of Permanganate of Calcium Upon the Toxins of Tetanus, Diphtheria and Tuberculosis.—The subject of the internal administration of antiseptics in the treatment of bacterial infections has been discouraged because of the well-known toxic effects of the latter on the organism. J. Baudran (*Comptes Rendus*, March 27, 1905), investigated the effect of calcium permanganate on various toxins, and found that it not only destroys their chemical identity, but also inhibits their physiologic effect. In the case of tuberculin it was found that while sodium and potassium permanganate does not interfere with the action of this toxin, the calcium salt markedly destroys its toxic effects.

PRESCRIPTION HINTS.

Hyperacidity of the Stomach.—In patients who persistently complain of acidity of the stomach associated with great discomfort or real pain it becomes necessary to counteract the hyperacidity by the frequent administration of alkalies. Ewald has obtained marked success by combining with the alkalies rhubarb and sugar.

℞ Magnes. ust.
Sodii carbonat. } aa gr. lxxv
Potassi carbonat.
Pulv. rhei ..... gr. cl
Sacch. lactis ..... ʒvii

M. Sig. Take three to five grains dry on the tongue every hour.

Chronic Gastritis.—In conjunction with lavage, and with galvanism should there be excessive gastralgia, the best results in the treatment of chronic gastritis may be obtained by the administration of cannabis indica, sulphate of codeine and nux vomica, especially when given in the following combination:

℞ Codeinæ sulphat. ..... gr. iii
Extract. cannabis indicæ ..... gr. ii
Extract. nucis vomicæ ..... gr. iii

M. et ft. pil. No. xii.
Sig. Take one three times daily after meals.

Delirium Tremens.—When the patient has reached the stage of alcoholic indulgence characterized by insomnia, great excitability and inability to retain food, it is best to administer an active cathartic as

℞ Pulv. jalapæ comp. ..... gr. x
Hydrarg. chlorid. mitis ..... gr. v
Sodii bicarbonatis ..... gr. v

M. Sig. On the tongue at once.

Should the heart show weakness, the following may be given with benefit:

℞ Tinct. capsici ..... ʒiv
Tinct. digitalis ..... ʒiv
Tinct. nucis vomicæ ..... ʒii
Spiritus ammon. aromat. ..... q.s. ad. ʒiii

M. Sig. Teaspoonful in water every four hours. The extreme nervousness and insomnia will require the milder sedatives or even the hypodermic use of morphine.

For Epistaxis.—

℞ Adrenalini chloride ..... gr. ½
Acid boraci ..... gr. xlv
Aquæ cinnamonie } aa ʒx
Aquæ camphoræ }
Aquæ destillatæ ..... q.s. ad. ʒiii

M. Sig. Instil into nostrils with a dropper ..

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, JULY 22, 1905.

HEAT PROSTRATIONS.

By the medical profession nothing significant has been contributed to the knowledge of heat prostration since Bennett Dowler, of New Orleans, clinically differentiated heat exhaustion for thermic fever, H. C. Wood, of Philadelphia, formulated the pathological theory, and Ira Van Gieson, of New York, demonstrated the histological changes in the cells of the brain and spinal cord. This accumulated medical knowledge is not available, as such, for the laity, but the ignorance which in many cases is responsible for heat prostrations should be combated, and in this item, as elsewhere, the medical profession should assume its function, so often emphasized of late, as an educator of the people and an advocate of prophylaxis.

When, however, in spite of exhortations to avoid the direct rays of the sun, to eat sparingly and to bathe frequently, prostrations occur, then it becomes incumbent upon the physician to bring to the emergency trained powers of diagnosis and accurate and efficient treatment. Absolutely essential is the differential diagnosis of heat exhaustion from thermic fever, the former being due to a vasomotor palsy of central origin, and the latter to a paralysis of the heat inhibitory center. Heat exhaustion is characterized by extreme prostration, collapse, restlessness, and in severe cases, by delirium. The temperature is often subnormal On the other hand, thermic fever usually sets in during exposure, with pain in the head, dizziness, oppression, nausea and vomiting. Sudden unconsciousness often initiates the attack, and the fever is usually extreme, not infrequently running to 112° F. However, such a temperature gives no grounds for despair, since a patient, admitted to the Presbyterian Hospital in New York, in August, 1896, with a temperature of 115° F., recovered. When it is borne in mind that heat exhaustion is a condition of prostration and collapse its treatment becomes sufficiently obvious, whereas in thermic fever the primary indication is to reduce the temperature as rapidly as possible. The most efficient means of accomplishing this is by the application of cold to the surface of the body, which was used in the New York Hospital as early as 1857, with excellent results. The cold bath is the form of application usually adopted. Other indications are met symptomatically.

Aside from the danger of immediate death, the physician must keep in mind the possibility of disastrous sequelæ. The most serious of these are insanity and meningitis, and the former occurs more frequently than is commonly supposed.

THE PANAMA SITUATION.

THERE is no dearth at present of large and significant matters to fill the public mind, and none perhaps which comes home more vitally to the American people than that which concerns the so-called Canal Zone of Panama. Governmental action there has been commented on by the general press in a spirit of more or less acrid criticism. This is what might be expected, since there is undeniably room for criticism, and the government is the legitimate target for it, in view of the specific concessions of the treaty now in operation. In brief, these concessions give complete and sovereign control over a "zone of land and land under water . . . extending to a distance of five miles on each side of the center line of the route of the canal . . . with the proviso that the cities of Panama and Colon and the harbors adjacent to said cities shall not be included within this grant." Article 7, too long to quote, further provides that in the cities mentioned the United States shall have absolute control as far as is necessary of all matters pertaining to sanitation. Consequently, ultimate failure to

secure workable sanitary conditions implies either insurmountable obstacles or else unwise or unscruplous action on the part of the officials in control. The chief obstacle encountered by the French in their attempt on the isthmus was the lack of authority to enforce sanitary regulations. This hampering factor has now been eliminated, and in contemporary parlance it is "up to" the American Government.

To be sure, there are natural obstacles of no mean dimensions. The problem of creating *de novo* in a tropical climate a sanitary system covering some five hundred square miles, including a population rapidly approaching 50,000, capable of protecting not only the native population but also the large alien element necessary to the officering of such an enterprise, will tax to the utmost the most competent sanitary experts. At the time when the United States assumed control, the towns and villages along the canal line were in a state of almost inconceivable filth, and the hospitals were entirely inadequate. One of the hospitals, that at Ancon, arranged on the pavilion plan, possessed buildings in a fair condition and situated favorably upon an elevation above the city. The company's hospital at Colon needed a thorough remodeling and repairing to make it available, and at best the capacity of these institutions was seriously disproportionate to the demands likely to be made upon them.

The chief diseases prevalent in the canal zone during the past year were beriberi, dysentery, malaria, tuberculosis and yellow fever. Of these the ones toward which sanitary measures must be directly aimed are malaria and yellow fever, for it is these that the alien is most likely to contract. The presence of yellow fever on the isthmus, though serious, has not become alarming, according to official reports, but the general prevalence of malaria is shown by the fact that microscopic examination of the blood of 669 individuals, selected indiscriminately, revealed in 340 the presence of some type of malarial parasite. From these investigations it is fair to conclude that approximately 60 per cent. of the population are thus infected. This statement assumes an added seriousness that we note that in the vast majority of cases, where the type of organism was definitely classified, it was found to be the æstivo-autumnal.

The two cities, Panama and Colon, included in the Canal Zone were found to be in imperative need of proper sewage system, and in the case of the latter a great difficulty is presented by its location. This city is built on a flat, sandy island, no part of which is more than a few feet above mean sea level. Some years ago the Panama Railroad Company built a small reservoir about two and one-half miles from the city, which supplies water "of an indifferent character" to the official quarter of Colon, the remainder of the population being limited to such rainwater as is collected from the roofs of the buildings. The difficulties of sewage disposal under such conditions are obvious.

In the face of these obstacles something, nevertheless, has already been accomplished. The hospitals referred to have been repaired and modernized, and another in Colon, hitherto under the control of the Panama Railroad Company, has been acquired. A large convalescent home for canal employees is also being equipped on an island in the Bay of Panama. Furthermore, in a recent interview, Mr. Shonts makes the following statement:

"Water has already been introduced in the city of Panama from spring-fed lakes. Panama has been sewered, the houses are being fitted with modern plumbing, and we have ordered I don't know how many millions of vitrified brick for paving. Colon will soon have its water supply from the mountains, and it will undergo the same process. Every house is to be fumigated and everything that human science can do will be done to stamp out the yellow fever. Oil has been spread over all the pools and swamps to kill the mosquitoes, the old seaweed has been torn up and thrown in the sun. In a dozen different directions the activities of the health officials are being exerted."

In view of the obstacles encountered and the comparatively short time which has elapsed, this would seem no trivial record. Dr. W. C. Gorgas, Colonel U. S. A., Chief Sanitary Officer, took up the task with a full realization of its difficulties. He himself said: "We shall, no doubt, meet with many disappointments and discouragements, and shall succeed in the end only after many modifications of our plans and after many local failures." Such an attitude presages better for the success of the undertaking than a more confident and less comprehending one. Dr. Gorgas has a right to speak with authority in such matters, for his accomplishment of the sanitation of Havana is still fresh in the public mind.

Naturally the methods so successful in Cuba are the ones to be applied here, and although the climatic and geographic factors are less calculable

it requires no very strenuous optimism to predict the ultimate success of these measures, namely, a systematic cleaning up of the terrain, an equally systematic destruction of the *Stegomyia fasciata* and *Anopheles,* together with their breeding places, and the treatment under screening of all infected or suspected cases.

The lax enforcement of quarantine regulations at the ports has also been replaced by a rigorous system of inspection, to the end that infectious diseases may not be introduced from abroad.

Another factor which might be classed as a natural obstacle, and one with which Dr. Gorgas had full experience in Cuba, consists of the distrust manifested by the native population toward hospital treatment and prophylactic measures. The overcoming of this distrust was one of the notable achievements of Dr. Gorgas's success in Cuba, and it is gratifying to note that a campaign of education, directed toward securing the coöperation of the native population of the Isthmus, bids fair to be promptly effective. "General faith in Dr. Gorgas," said one of the employees, "is the only thing that keeps any of us on the Isthmus."

Yet at the present moment, in spite of the precautions thus far taken, reports from the isthmus are none too encouraging. Even after allowance has been made for panic and natural exaggeration it must nevertheless be admitted that yellow fever is still endemic, and that the mortality and sickness have increased. The isthmus is not yet a safe and healthy dwelling place for either the native population or the immigrant. Yet until such a condition is attained, the vast engineering scheme upon which the government has embarked must remain in abeyance. As the chairman of the committee justly remarks: "Our first duty is to create sound underlying conditions. This is now vastly more important than the moving of dirt."

That President Roosevelt strongly concurs in this view of the situation is shown by his remarks before the Associated Physicians of Long Island on July 12, at Oyster Bay. He, too, recognizes the difficulties. Among other things he said:

"Now, of course, in doing a great work like that in the tropics, in a region which, until this Government took hold of it, was accounted to be a region exceptionally unhealthy, we are going to have trouble, have some yellow fever, have a good deal of malaria fever, and suffer more from the latter than from the yellow fever, although we will hear nothing like the talk about it. What is being done in Panama is but a sample of the things that this country has done during the last few years, of the things in which your profession has been so prominent a part. Take what we did in Cuba, where we tried the experiment which had not been tried for four hundred years, of cleaning the cities. One of the most important items of the work done by our Government in Cuba was the work of hygiene. This country has never done better work, that is, work that reflected more honor upon the country, or for humanity at large."

Mr. Roosevelt further emphasizes, as does Mr. Shonts, the fact that the gloomy reports brought back from the isthmus emanate either from persons who should never have gone there at all, or from those who were not assigned to proper work on their arrival.

The general public, with characteristic impatience for results, betrays a slight inclination to become disheartened over the Panama situation. Yet a fair and reasonable estimate permits a forecast far from gloomy. If the authorities, concurring with Mr. Shonts, that sanitation must precede excavation, give Dr. Gorgas a free hand to push the work in this direction as speedily and thoroughly as possible, and if only those set out for the isthmus who know where they are going and what they are going for, who possess a mental equilibrium proof against panic and a physique reasonably capable of withstanding the environment, then the construction of the Panama Canal may proceed to completion without any appalling sacrifice of human life.

In short, the proper view of the situation preserves a balance between irresponsible optimism and premature pessimism, the sane, clear-sighted attitude which estimates the difficulties at their proper magnitude, calculates adequate measures for their removal and makes haste slowly toward the desired goal.

THE EXUDATIVE DIATHESIS.

THERE is a manifest tendency, on the part of modern clinicians, to reject certain morbid conditions as distinct pathological entities, and to include them under larger groups, as mere variations of the same fundamental process. To the larger groups the term diathesis is applied, and to the already numerous list of diatheses, a new one has been added. Professor A. Czerny (*Jahrbuch f. Kinderheil.,* January 2, 1905); whose opportunities for observation in the children's ward of Breslau are unexcelled, is the author of this new expression, the "exudative diathesis." This

term connotes no new disease, but is meant to include a large number of conditions that are observed among young children, which, while individually they are apparently trifling, are nevertheless the cause of considerable anxiety to the pediatrist.

These conditions have been hitherto classified under the rather indefinite "scrofula" of the older writers. One hears very little of this disease nowadays, for many of the cases which have formerly been diagnosed as scrofula are now recognized as tuberculosis, in its myriad forms. Yet not all cases of scrofula are tuberculosis. There is still a good deal of difference of opinion as to the proper boundary-line between the two diseases. In order to avoid the confusion attending the use of the older word, Czerny rejects the term scrofula and applies to many of the cases that have been included under it, the expression, "the exudative diathesis."

This condition rests upon a marked hereditary basis. In most cases, however, the parents do not recall or are ignorant of the fact that they themselves had evidences of this constitutional disorder during childhood or infancy. In the same family different children may show widely diverse manifestations of this affection, which may, in fact, express itself in a multitude of ways.

Among these manifestations the most common is the so-called "geographical tongue." This is really an exudation into the mucous membrane covering the latter organ, which may disappear and reappear haphazard on various parts of the tongue. Another common symptom is the seborrhea of the scalp in infants, which primarily is simply an exudation beneath the skin, but owing to irritation is frequently converted into an eczema. Of similar nature is strophulus, which is usually found upon the cheeks, principally in fat infants, and is often the forerunner of facial eczema.

The above cutaneous lesions may be compared to the exanthem of infectious diseases, and like them have frequently associated with them an exanthem, or eruption on the mucous membranes. These epithelial lesions are exceedingly prone to irritation and consequent infection and accordingly one sees commonly a tumefaction of the cervical lymph-nodes. This explains the enlarged glands of the already obsolete scrofula. These, together with the above sources of infection, may become the portal of entry for tuberculosis. Hence one can understand the confusion of the older writers in confounding tuberculosis with scrofula, and characterizing both as primary diseases, whereas they are really secondary to the exudative diathesis.

The geographical tongue, seborrhea of the scalp, and strophulus are seen in infants less than one year of age. Older children display, as a rule, quite different expressions of the exudative diathesis. In them are found a tendency to repeated attacks of follicular tonsillitis, which, recurring at regular intervals, cannot be attributed to mere exposure, but must be assigned to some constitutional dyscrasia. In many of these children are found hypertrophy of the lymphoid follicles of the nasopharynx, and in some of them occur periodical attacks of croup.

The frequency of secondary complications that occur in the course of the exudative diathesis, such as enlarged glands, tuberculosis, etc., renders the subject of treatment of this condition of extreme importance. One should avoid a diet that has a tendency to make the child too fat. The country-air has a favorable effect on the disease, while the city-air, with the accompanying crowding and ill-ventilation, favors its development.

ECHOES AND NEWS.

NEW YORK.

Ambulance Accidents.—Three accidents to ambulances, besides one runaway, which fortunately did no damage, is the record of the past week.

Rich Gift to Hospitals.—The will of Margaret A. Jones, filed for probate July 15, divides her residuary estate, which will probably be more than $900,000, in equal shares among St. Luke's, the Presbyterian and the Post-Graduate hospitals of this city. The principal of the share going to St. Luke's is to be known as the Margaret Jones fund, in memory of Miss Jones's mother. That going to the Presbyterian will be known as the Margaret A. Jones fund, and the Post-Graduate devise will form the David Jones fund, in memory of Miss Jones's brother. The incomes of these funds are to be used in providing free beds.

Ship Had One Plague Case.—Capt. Williams, of the British steamship Indrani, which arrived July 17 from China and Japan, reported to Health Officer Doty, at Quarantine, that a month ago, at Suez, one of the ship's crew, a Lascar, was taken ashore ill apparently of bubonic plague. On Saturday, about forty miles off this port, another Lascar died and was buried at sea. The captain said this man did not have the plague. Dr. Doty made a careful examination of the crew of forty-eight men, all Chinese and Lascars, and found that none was ill. As a precautionary measure, however, he decided to send all hands to Hoffman Island for observation.

"Beauty Doctor" Arrested.—Dr. Andrew L. Nelden, of 13 East Twenty-ninth Street, who maintains an "Institute and Sanitarium for Plastic Featural Surgery," was arrested last week on the charge of

obtaining money under false pretenses. The complainant was Mrs. Josephine Ware, of Denver, Colo., who charges that he contracted to smooth out wrinkles on her face and forehead, and after more than six weeks' treatment left her face badly scarred. Three other out-of-town women have made complaints to the District Attorney's office that they were similarly treated. Three women and a man, all patients, were found in Dr. Nelden's house when he was arrested. Innumerable letters were found at the "Institute" complaining of the results of his treatment. He is the same man who made such a successful bid for notoriety a few years ago by advertising for an ear, claiming he wanted to graft it upon a patient.

Enlarging Ellis Island.—Work was begun July 20 on the first crib for the outer retaining wall of the Ellis Island extension, which the Department of Commerce and Labor is making for a hospital site for contagious diseases among immigrants arriving at this port. At present all contagious cases among immigrants landing at Ellis Island are cared for by the New York Health Department at North Brother Island, under a contract with the Federal authorities. Over a year ago Health Commissioner Lederle notified Immigration Commissioner Williams that this contract would have to be abrogated, because the city had not the facilities for handling the large number of cases sent from Ellis Island, in addition to its own cases. The extension, for which the Government appropriated $100,000, is to be an island 800 feet long, 250 feet wide, with a basin 250 feet wide and 1,100 feet long, between it and the present hospital island. The contractors have 250 days in which to complete the work.

Trachoma Among Immigrants.—Since the first of June there has been a marked increase in the number of cases of trachoma among the immigrants arriving at Ellis Island. As a result not only a majority of the patients in the hospital at the island are held there because of this disease, but about one-third of those who are cared for, among the overthrow in the Long Island Hospital, are trachoma cases. Dr. Stoner, chief of the Marine Hospital Corps on Ellis Island, who has just returned from a tour of inspection along the Canadian border, visited the Long Island Hospital to inspect the immigration cases there. Speaking of the increase of trachoma during the past two months, he said: "It looks to me as though they had been held up on the other side until they secured a favorable opportunity to rush them into this country, and than all were shipped over in a bunch. Most of the cases we have held up during June and the early part of this month are from Mediterranean ports, and, as some of the ships were overdue in arriving here, it happened that we got an unusually large number of people from that section in groups. Invariably there were many trachoma cases, and the fact that they came in this way makes me think there was a concerted movement to work them into the country."

Superintendent of Bellevue.—As we anticipated in our last issue, the trustees of Bellevue and Allied Hospitals on July 13 appointed Dr. Samuel T. Armstrong, medical director of the Washington Life Insurance Company, superintendent of the city hospitals. Dr. Armstrong, although second on the civil service list for the place, was the choice of Dr. John W. Brannan, the president of the Board of Trustees. Dr. Armstrong has had a great deal of experience in the construction of hospitals in Cuba and the Philippines, having served as a surgeon in the army and in the United States Marine Hospital Corps. The trustees think his experience in that line will be of particular value in the construction of the new Bellevue Hospital, the bids for which have already been received. Dr. Armstrong was born in St. Louis forty-five years ago and received degrees from the St. Louis Medical College and the St. Louis University. After ten years' service in the Marine Hospital Corps he came to New York, in 1890, and was made visiting surgeon to the Harlem and Willard Parker hospitals. At the outbreak of the Spanish-American war he entered the army as Surgeon-Major. He resigned in 1901. Work on the new Bellevue Hospital will be commenced as soon as the trustees receive an opinion from the Corporation Counsel on their right to accept alternative bids; that is, bids wherein materials are substituted other than those provided for in the specifications.

City Consumptive Hospital.—Health Commissioner Darlington has obtained from the Board of Estimate an appropriation of $250,000 for the establishment of a tuberculosis sanitarium at Mount Hope, in Orange County, N. Y. As a result of his investigations he recommended to the Board of Estimate the purchase of 1,200 acres on the summit of Shawangunk Mountain. The site is about seventy-seven miles from this city and twenty-five miles from the Hudson River, back of West Point. It is 1,250 feet above the sea level. Dr. Darlington informed the board that he had succeeded in obtaining the necessary consents for the use of the place as a sanitarium for consumptives, and, upon hearing that, the appropriation was at once granted. The land is now occupied by farmhouses and cottages, and it is the intention of Dr. Darlington to use these for the accommodation of patients immediately without waiting for the building of the large hospital and cottages. With the houses which will be at his disposal at once Dr. Darlington said yesterday that he could take care of at least 400 patients. It is his intention to treat only incipient cases of tuberculosis. The Commissioner explained that there are in this city something like 25,000 consumptives, and that in order to help these sufferers it would be the object of the sanitarium to spread information as to the habits and treatment of persons afflicted with the disease should follow.

PHILADELPHIA.

Dies of Sea-Sickness.—An immigrant girl from Hungary, who just landed in this country, died in the Altoona Hospital, of sea-sickness. Soon after the steamer sailed she became ill and grew steadily worse. When she landed at Ellis Island the girl was not able to stand.

Hospital Crowded.—The Jefferson Hospital is so crowded that no new cases can be taken in at the present time. Emergency cases will be treated and then transferred to other institutions. The repairs which are being made in the medical and children's wards are largely responsible for the crowded condition.

Sanitarium for Consumptives Must be Abandoned.—Because of the petition of complaint filed by the residents of Mt. Airy against the establishment of a sanitarium for tuberculous patients in that neighborhood, Judge Beitler made a personal investigation of the neighborhood. He decided that the institution could not remain upon that plot of ground, since there is a clause in the deed which prevents the establishment of saloons, factories, or anything that may affect the health and comfort of the neighbor-

hood. The Judge said that he was convinced Miss O'Hara is doing her best to make the institution as little annoyance to the neighbors as possible.

Medical Inspectors Make House-to-House Visits.—Director Martin, of the Department of Health, has detailed the entire corps of assistant medical inspectors to visit the homes of the poor and to give the mothers instruction as to the care of infants during the warm weather. When a child needing medical treatment is found it is reported to a ward out-door physician of the Bureau of Health. In order to avoid an outbreak of smallpox the inspector will determine whether or not the persons visited should be vaccinated. In the event that they refuse such an operation their employer will be notified that such persons are a menace to the health of his employees. Their discharge will be requested.

CHICAGO.

Fresh Air Tent House for Children.—The Chicago Relief and Aid Society is making a new experiment in charitable endeavor, by establishing fresh air stations for sick babies in the poorest and most densely populated sections of the city. A small structure of wood and canvas has been built and appropriately termed a "tent house," on the grounds of the Northwestern University Settlement. The Visiting Nurses' Association has volunteered to supply a corps of nurses to attend the little ones, and several hospital physicians have given their services, so that the best of care is guaranteed the inmates. Sterilized milk is furnished by the Children's Hospital Society, and the officers of the University Settlement have given the use of the kindergarten bathrooms, and another large, airy room that is to be used to accommodate the babies for whom there is not enough space in the tent house. If the plan proves successful it is the intention to establish a large number of similar institutions through the congested districts.

City Water Supply.—Since the excessive precipitation of May (5.14 inches, as against the thirty-odd years' May average of 3.75 inches) there has been a marked depreciation of the sanitary quality of the public water supply. During April the supplies from all sources averaged 88.4 per cent "safe;" in May the average was 56.9, and in June only 53.3 per cent. "safe." The effects are seen in an 88 per cent. increase of the deaths from the acute intestinal diseases—contributed to largely by the increasing temperature. During the first fifteen days of July the average of the supplies from all sources has improved to 78.8 per cent. "safe." That from the Ashland Avenue pumping station—although supplied from the same intake as the Chicago Avenue and the Harrison Street stations—continues unaccountably bad. It has averaged only 18.2 per cent. "safe," while that from the other two stations on the same supply lines has averaged 81.8 per cent. "safe." Investigation by the City Engineer is being made for what is, undoubtedly, some local cause for this pollution.

Fourth of July in Chicago.—Notwithstanding the strenuous efforts of the medical profession and of the press, both lay and professional, Four-of-July casualties continue to increase year by year. As tabulated July 6 of last year they numbered 2,431 for the whole country. On the same date this year 3,160 had been reported—an increase of 30 per cent. Of these totals there were 103 in Chicago last year and 132 this year—substantially the same proportion of the total in each year. Up to July 15 of each year there had been 100 deaths from these accidents in 1904 and 92 in 1905. The death-rate last year was, therefore, 4.1 per cent;. this year it was only 2.9 per cent. Had the death-rate of 1904 obtained this year there would have been 129 deaths among the 3,169 casualties, instead of 92. This reduction of nearly 30 per cent. in the death-rate is to be attributed solely to the improved treatment of this class of wounds, advocated persistently by the department for many years. It is, however, not at all flattering to civic nor to professional pride to note that—while the death-rate of all cases in 1904 was 4.1 per cent. the rate of the Chicago cases in that year was 10.7 per cent.; this year the respective rates are 2.9 per cent. of all cases and 9.9 per cent. of Chicago cases. Obviously, there is urgent need of further efforts in this city.

GENERAL.

Appointment of Dr. Ray.—Dr. Wyeth E. Ray, Yale Medical School, '98, has been appointed Associate Medical Director of the Travelers' Insurance Company, of Hartford, Conn.

Appointment of Dr. Ohlmacher.—Dr. A. P. Ohlmacher has been appointed Director of the Biologic Laboratories of Frederick Stearns & Co., of Detroit, Mich., and has entered upon the active duties of the position.

Smallpox Kills 3,279.—The statistics of the smallpox in Valparaiso, Chili, from January 1 up to the 10th of the present month show 3,279 deaths. A report dated July 15 says during the last forty-eight hours 104 new cases have been reported. Twenty-two bodies were picked up in the streets yesterday. Typhus fever and chickenpox have broken out in Santiago, assuming epidemic proportions.

A Doctor in Cabinet.—The American Medical Association, in convention at Portland, Ore., adopted a resolution offered by Dr. Liston H. Montgomery, of Chicago, advocating the creation of a new Cabinet place, to be known as the Department of Public Health, the secretary of which is to rank with other Cabinet officers. The resolution calls for more stringent laws for the prevention of diseases, and urges Congressional action.

International Medical Congress.—The next International Medical Congress will be held in Lisbon, April 19 to 26, 1906. It is expected that it will be one of unusual importance, for a meeting which will be held in what has always been considered as an out of the way country. Already the titles of papers from some of the most distinguished men of the medical profession have been received. Many interesting topics for discussion have been selected by the executive committee.

Dr. Burnham to Head Consumption Hospital.—The Board of Managers of the New York State Hospital for the Treatment of Incipient Tuberculosis has appointed Dr. Melvin Page Burnham, of New York City, acting superintendent, to succeed Dr. J. H. Pryor, resigned. Dr. Burnham has been for three years resident physician of Seton Hospital at Spuyten Duyvil, a tuberculosis sanatorium of 300 beds. He is highly recommended by New York experts.

Changes in the Pharmacopœia.—In the new United States Pharmacopœia the following changes are noted: The strength of tincture of aconite has been reduced from 35 per cent. to 10 per cent., and that of tincture of veratrum from 40 per cent. to 10 per cent. The strength of tincture of strophanthus has been increased from 5 per cent. to 10 per cent. These changes officially go into effect on September 1, 1905.

New Hospital for Brooklyn.—Charities Commissioner Tully has purchased a piece of property in Dumont Avenue, between Bradford Street and Miller Avenue, in the East New York district, Brooklyn, as the site for the new hospital which is to take the place of the Bradford Street Hospital. The building will have a frontage of 200 feet on Dumont Avenue and a depth of 280 feet. It is Mr. Tully's intention to build only a small structure at first, at a cost of $60,000, so designed as to permit the erection of wings later on.

Death Total on Railroads.—Accident Bulletin No. 15, just issued by the Inter-State Commerce Commission, giving an account of railroad accidents in the United States in January, February, and March, 1905, shows that in that period 28 passengers and 204 employees were killed and 1,651 passengers and 2,062 employees hurt in train accidents. Other accidents to passengers and employees, not the result of collisions or derailments, bring the total number of casualities to 909 killed and 14,397 injured. The total number of accidents was 1,787 collisions and 1,321 derailments. The damage to cars, engines, and roadway by these accidents amounted to $2,449,248.

Queen's New Red Cross Society.—The King and Queen lately inaugurated the formation of a new Red Cross Society, to cooperate with all existing societies in succoring the sick and wounded in time of war. The council appointed the Queen president and Lord Rothschild chairman. At a meeting at Buckingham Palace the Queen made a speech, briefly outlining the objects of the society. In conclusion she said: "I now appeal to all the women of the empire to assist me in carrying out the great scheme, which is essentially the work of women, and which is the one only way in which we can assist our brave and gallant army and navy to perform their arduous duties in time of war."

Next Meeting of the American Medical Association.—The next meeting of the American Medical Association will be held in Boston. The following officers have been elected: President, Wm. J. Mayo, Rochester, Minn.; Vice-Presidents, First, Walter Wyman, Surgeon General; Second, K. A. J. Mackenzie, Portland, Oregon; Third, Edmond D. Martin, New Orleans; Fourth, Eugene S. Talbot, Chicago; General Secretary, George H. Simmons. Medical oration, Frederick G. Shattuck, Boston; surgical oration, Joseph D. Bryant, New York. Board of Trustees (for three years), E. E. Montgomery, of Pennsylvania; H. L. E. Johnson, of the District of Columbia, and A. L. Wright, of Iowa.

Typhoid Fever of Hamlet.—The little hamlet of Collinsburg, about twenty-five miles from Pittsburg, Pa., is undergoing a scourge of typhoid fever, and conditions are of the most distressing character. There are only about thirty houses in the place, and there is not one of them in which at least one case of the fever cannot be found. In some of the homes there are as high as five cases. One man, named Litt, has lost five of his children since the epidemic started, and other families have lost three and four members. Physicians have labored faithfully, but they appear unable to abate the plague or lessen the fatal results of the attacks. Between death and fright the place bids fair to become depopulated. The cause of the epidemic is supposed to be a foul water supply, together with unsanitary conditions.

Day Sanatorium.—A day sanatorium for the treatment of tuberculous patients has been opened on Parker Hill, in Roxbury, Mass. Those needing treatment are driven to the sanatorium and are permitted to spend the day there. This plan will be followed as late as October, if all things permit and sufficient money can be raised from friends outside. Steamer chairs of canvas and others allowing a more upright position were placed under the trees in a most inviting way. Beyond, was the "rest tent," showing couches for those who feel the need of sleep or protection from the weather. During the morning each patient was examined as to pulse and temperature. This will be done every day; weights will be taken twice a week and more thorough examinations made at the end of every month in order that records of each case may be complete. There is a possibility that this section may be too high for some of the patients, but as all are in what is called the "hopeful stage," it is believed that they will all be benefited. There will be practically no medical treatment, although there is every provision for emergencies. Dr. David Townsend, of Brookline, has the general medical supervision of the whole undertaking, with Dr. F. R. Tower on duty during July and Dr. G. W. Hall through August. Dr. E. O. Otis, a recognized authority on treatment for tuberculosis; Dr. Frederick Knight and Dr. H. C. Clapp are the consulting physicians. Mrs. Mary Kehew, Mrs. C. A. Cummings, Rev. P. R. Frothingham, T. M. Clark and G. S. Mumford are among those who are actively interested in the success of this most important undertaking The grounds of the sanatorium were arranged by A. M. Wilson, the secretary of the association, and Mr. Clark.

Home Sanatorium.—A tuberculosis class, or home sanatorium, will be established under the auspices of Emmanuel Church of Boston, consisting probably of not more than fifty members. It is important that the number of patients should be limited in order that the careful supervision so necessary to success may be secured. The object of this plan is to carry out the sanatorium methods in the homes of the patients. Dr. Charles L. Minor, of Asheville, has shown that the hygienic regimen may be employed with success outside of a sanatorium if sufficiently detailed instructions are given and strict discipline maintained. His work has been among the well-to-do educated classes. We believe that equally good results can be obtained in the homes of the intelligent poor. It is known that too great value has been attributed to climate in the treatment of tuberculosis. As has been well said care without climate is more important than climate without care. It is far better to provide the poor consumptives in this locality with facilities for leading an out of door life and with nutritious food than to send them away to a more favored climate, where, however, healthful surroundings, good food and proper medical attention are beyond their slender means. Our work will not duplicate that of existing organizations. It is a supplement, not a substitute, for the tuberculosis dispensary, and is intended for those who are unable to receive the benefit of treatment in the State sanatorium. The essential features in the sanatorium treatment are: (1) Facilities for living an out of door life in all sorts of weather; (2) good food; (3) careful regulation of the details of daily life. The necessary supervision will be maintained by (*a*) frequent visits of the nurse, and occasional visits of the physician; (*b*) weekly meetings in the examining room of the class; (*c*) the individual record book in which each patient will enter the essential details of the day, *e.g.*, the number of hours of rest, the amount of exercise, the diet, and if necessary the temperature. It is essential that each patient should have facilities for living and sleeping out of doors. These may be secured by moving to the upper floor

of an apartment or tenement with a flat roof, so that the patient can live on the roof. The full amount of available sunshine will thus be secured and an atmosphere relatively free from dust. Many of the newer tenement and apartment houses have flat roofs. Some families may prefer moving to the less crowded suburban district where it will be possible to live on a veranda or in a tent. The patients will be aided in providing themselves with bed-tents, shelters from winds, reclining chairs and the proper wraps and coverings, in order that the outdoor life may be comfortable in all sorts of weather. A carpenter will be specially trained to make balconies and tents of the most approved design and these will be provided at the lowest possible cost. Instruction in the nature of the disease and the prevention of its spread will be given. Those in charge of the patient's food will be taught its proper preparation and in special cases, milk, butter, oil and eggs will be furnished. The class will be under the direct supervision and management of Drs. Joseph H. Pratt and John B. Hawes.

A. M. A. Echoes.—Dr. George H. Simmons, the secretary, submitted a concise report containing much interesting information. The establishment of the card index system, biographical in character, was described as being carried forward through the assistance and with the cooperation of medical colleges and secretaries of State licensing boards. The membership on the date of the last report, June, 1904, was 15,334. During the year there have been added 4,889, and 938 have been dropped, 162 on account of death, 176 not eligible, 36 for non-payment of dues, 535 resigned, and 29 were not found, leaving a net gain of 3,951. This makes the total membership on June 1, 1905, 19,285. It is estimated that there are about 17,000 subscribers not members.

From the special committee on National incorporation was received an exhaustive report reviewing the efforts to secure through an act of Congress incorporation of the American Medical Association, the recommendation of which was contained in this brief resolution recommended for adoption: "Resolved, that the efforts to secure National incorporation of the American Medical Association be and hereby are continued, and that the labors relating thereto become a part of the duty of the Committee on National Legislation, and that these duties be no longer referred to a special committee appointed for that purpose."

Secretary Simmons read a recommendation by which contract doctors in the United States Army should be placed on a ranking list, rather than spend their time "avoiding slights." By the same token the dental corps was also recommended for receiving a certain rank.

Reports were received from the committees on the Rush monument and the Walter Reed memorial fund, the former announcing completion of its work, the unveiling of the monument, and begging to be discharged, and the second reporting the sum of $18,065.75 subscribed and all except $1,871 paid, and asking to be continued for at least another year.

Whether the American Medical Association should publish a medical directory, and, if so, whose names it should contain, was a topic of discussion before the house of delegates. The matter was finally left to the Board of Trustees, and that organization had already come out advocating a directory giving the names of all practitioners licensed by the States. When the directory is published it will be composed of all the licensed doctors, with the members of the Medical Association in black-faced type, to herd the sheep from the goats, as they themselves expressed it.

Eloquent, scholarly and impressive was the memorial address delivered by Dr. Henry O. Marcy, of Boston, on the late Dr. Nathan Smith Davis. The speaker paid tribute to the life work and character of the founder of the Association. He reviewed carefully the early biography of his subject, born in 1817, in New York State, his youth passed on a farm, and received an education in the public schools, for a short period in the seminary at Cazenovia, and at the age of twenty graduated from the College of Physicians and Surgeons of the Western District of New York. He began practice in Binghamton, later removed to New York City, and was the founder of the American Medical Association, being the founder and editor of various of the leading medical journals. In 1849 he transferred to the Rush Medical College, at Chicago, and from that time identified himself actively, not only with teaching, but with almost every sanitary, scientific and educational interest of the city. In 1859 he became the active head of what is now known as Chicago Medical College.

OBITUARY.

Dr. Edward S. Wood, Professor of Chemistry in Harvard Medical School, died at his summer home in Pocasset, Mass., on July 11, from cancer of the intestines. He was one of the most famous chemists in America and an authority on analysis of human blood He was an expert witness in many murder cases in which the identity of blood stains figured, including the Blindin, Mate Bram and Tucker trials.

Dr. William Armisted Moalt, a member of one of the oldest families of Maryland, died at the Johns Hopkins Hospital, on July 12, after an operation for appendicitis. Dr. Moalt was a descendant of Ellen North, the first white child born in Maryland. He wrote several books on medical subjects. He had large business interests in the management of his estate and the holdings in this city of his sisters, Mrs. I. Townsend Burden and Mrs. Robert I. Cutting, of New York.

Dr. Clado, a Greek physician long resident in Paris and a Chevalier of the Legion of Honor, died July 10, as a victim of duty. He returned late at night from Chantilly a few days before, where he had accompanied the Crown Prince of Greece on an automobile trip, and went to a hospital and performed an operation on a poor workman because he conscientiously refused to postpone the operation till the next day. During the operation he slightly pricked his finger. Blood poisoning developed a few days ago, and in spite of the best medical attention the case proved fatal.

Dr. A. Palmer Dudley, of New York, Professor of Gynecology in the Post-Graduate Hospital, the Harlem Hospital and the Medical School of Vermont University, died July 15, in Liverpool, England, while on his way to attend the International Medical Congress at St. Petersburg, to which he had been appointed a delegate from the United States. Dr. Dudley was born in Phippsburg, Me., in 1853, and received his medical education at Dartmouth Medical School. He was attending surgeon at the Harlem Hospital and the Randall's Island Hospital, as well as Professor at the Post-Graduate. He was a member of many medical societies and the author of various professional articles. The body will be brought back to Phippsburg for burial. Dr. Dudley had obtained passage on the Oceanic for July 5. A few days before the date of sailing he showed symptoms of pulmonary tuberculosis.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-sixth Annual Meeting, held at Portland, Oregon, July 11, 12, 13 and 14, 1905.

FIRST DAY—JULY 11TH.

GENERAL SESSION.

The meeting was formerly opened by prayer by Rev. A. A. Morrison, of Portland. The retiring President, Dr. Musser, then introduced Judge Meloin George, of the Supreme Court of Oregon, who represented the Governor in welcoming the visiting physicians to the State. Judge George said that in California they had elected a physician Governor and that there were many physicians in Oregon who should be Governor. He invited the visitors to stay for good in the glorious climate and the wonderful prosperity of Oregon which its citizens were too modest to try to keep to themselves.

Dr. Harry Lane, the Mayor of Portland, himself a physician, then added his welcome to the city. He told the story of efforts to improve the moral and hygienic conditions of Portland for the Exposition time and assured the doctors that they should be the welcome guests of the city and its citizens.

On behalf of the Oregon State Medical Society, its President, Dr. George F. Wilson, bade the visiting physicians welcome and hoped that they would appreciate the Exposition and the expansion of the State as well as transact their business and share in all the social functions.

Dr. Henry W. Coe, the President of the City and County Medical Society of Portland, then stated some of the reasons why the physicians should feel themselves welcome in the metropolis of the Northwest. When it was announced that the American Medical Association had resolved to come to Portland for their annual meeting, it was stated that at least $20,000 must be raised to provide proper arrangements for the meeting. Portland is not a large city, nor is it blest with many very wealthy men, but there was a prompt response to the call for funds. Three thousand dollars was subscribed by six physicians at the first meeting. When the inhabitants of the city were told that an effort was making to secure the meeting of the most important scientific body of this country, or perhaps of the world, the response was prompt. Before the opening of the session $23,000 was in bank to defray the expenses.

Dr. Mackenzie then announced the social features of the meeting: The reception at the American Inn on the Exposition grounds on Tuesday evening. The reception at private houses as well as that to Dr. McMurtry, the President of the American Medical Association, on Wednesday evening in the Oregon Building, and the trip down the river on Thursday. The reception at "The Oaks," given on Thursday evening by the Portland City and County Medical Society, assisted by the District and State Medical Societies. Finally the trip arranged for members to Alaska, to be taken just after the close of the meeting; as well as the Friday morning trip up the Columbia River.

Dr. Musser then presented Dr. Lewis S. McMurtry, of Louisville, Ky., the President-elect of last year, who delivered the President's annual address (See page 97).

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY—JULY 11TH.

The Chairman of the Section, Dr. Richard C. Cabot, of Boston, in the chair.

The scientific business of the session began with the reading of a paper on "The Incidence of Heart Disease in San Francisco," by Wm. Fitch Cheney, of California.

Statistics of Heart Disease.—Dr. Cheney analyzed 135 cases of heart disease that had been under observation in an out-patient clinic. By far the most frequent lesion seen was that of the mitral valves causing insufficiency. After this came aortic insufficiency and then mitral stenosis in some nine cases. Only patients above twelve years of age were received at the clinic, or it seems not unlikely that increase of uncomplicated mitral disease would have been seen. Most of the patients under observation were under twenty years of age and all were under thirty years. It is particularly in early life that acute articular rheumatism and other infectious diseases cause mitral thickening with stenosis. Most of the aortic disease was seen in those suffering from arterial disease, and Dr. Cheney called attention to the fact that aneurisms of the aorta are especially common in San Francisco.

Etiology.—In valvular disease the most common cause was evidently rheumatism. This was not a common factor in myocarditis, however. Most of the cases had suffered from recurring attacks of rheumatism and some were in the midst of a relapse into rheumatism when they came under observation. Race and sex seem to have an influence in predisposing to heart disease only inasmuch as they influence the habits of the individual. Three-fourths of the patients were foreigners, but these are the hard workers who, besides neglect hygiene and overindulgence in alcohol and tobacco. Very few hard workers who are careless in their habits escape aortic disease. Less than one-third of the cases occurred in women, showing the influence of their quieter lives. The particular occupation seemed to bring with it liability to heart disease, though hard work is an important factor.

Septic Arthritis and Vulvulitis.—Dr. Op[illegible]ls, of California, in the discussion, said of Dr. Cheney's paper, that in making the autopsies on some of these cases the most prominent feature was the frequency of septic conditions. Some of the valve lesions were of distinctly ulcerative character, though the clinical diagnosis had been rheumatism. It seems probable that many cases in which endocardial complications occur that have been called rehumatism are really of septic origin. True, simple articular rheumatism, simple arthritis, may run its course without the occurrence of bacteria in the joints and consequently without danger of heart complication.

True and False Rheumatism.—Dr. James J. Walsh, of New York, said that no movement in medicine at the present time is more interesting than the separation of so-called rheumatism into its constituent diseases. The best sign that true rheumatism has been present is that it leaves no mark in the joints. When the joints are permanently injured then either the disease was not simple rheumatic arthritis or it was complicated by some accessory bacterial infection. Septic arthritis is undoubtedly much commoner than has been thought. Gonorrheal rheumatism is quite frequent. The heart valves are really joints in the tissues, covered with serous membrane, to prevent function and adhesion. We should not expect them to suffer permanently from true rheumatism any more than the joints. Where endocarditis occurs there must be the suspicion of a complication in the case. Rheumatism, as now used in medicine, is a multiplex term covering many different affections, of which any simple arthritis really deserves the name. Proper limitation will bring progress in diagnosis, and improved methods of differentiation will lend further precision to our efforts

Hard Work and Aortic Disease.—Dr. Grandee, of Norfolk, Virginia, said that many of the negroes who work about the docks at Norfolk suffer from heart disease. They are not especially liable to rheumatism but, on the contrary, suffer from the disease rather infrequently. Many complain of the vague pains commonly called chronic rheumatism, but have no history of an acute febrile disorder with swollen joints. Their pains are nervous in character or are myalgic. They are all truckers, that is men who do heavy lifting around the docks, and their heart disease is evidently due to the strain put upon the valves. It is rather of traumatic origin than the result of spreading arteriosclerosis.

Secret Nostrums.—Dr. Frank Billings, of Illinois, called attention to the large number of secret nostrums, copyrighted preparations, that are advertised in the medical journals of this country and, as advertising costs money, are evidently prescribed by the American medical profession. The real patented preparation may have an ethical place. The patent is granted for some feature of the manufacture. This is protected only for seventeen years, while the copyright affords protection indefinitely. It is evident to any right-minded physician that these secret nostrums should not be prescribed, yet thoughtlessly and through inaction they have secured a great vogue.

Cause of Evil.—Dr. Billings considers that the cause of the evil lies in the deficient teaching of pharmacology and therapeutics. Altogether too little is said of treatment and there is no practice in prescription writing. While diagnosis, bacteriology, and pathology with anatomy and physiology are occupying so much time, the claims of pratical medicine are neglected. Too often a drug nihilism is the spirit of the medical teaching. Students should be taught insistently the value of single remedies and of simple combinations. Only by this will the root of the present evil, which is fastened in ignorance and nourished by the disinclination to think, be effectively reached. Meantime there are certain fomenters of the soil that can be made less fruitful of harm than at present.

Unethical Medical Advertising.—Most of the medical journals that come to the doctor's desk contain these nostrums advertised. The reputable pharmacists taught the lesson of calling exaggerated attention to the effectiveness of their preparations and the nostrum manufacturers followed suit and went them several better. One-half of the medical journals would go out of existence if such advertising were stopped. They could well be done without, however. At present most of the journals represent not the profession nor their editors, but their advertisers. This must be stopped if a serious evil is to be eradicated.

Dr. Musser, in opening the discussion, said that skepticism in therapeutics, especially in the use of old-time remedies, is undoubtedly responsible for much of this evil. A definite return to the prescription of old-fashioned remedies, even the so-called galenicals, would do away with this. Meantime the movement to lessen the prominence of the nostrum evil and the shame of their advertising must be encouraged in every possible way.

Resolutions.—Dr. Alfred Stengel, of Philadelphia, said that the American Medical Association now represents nearly 20,000 members. Some 15,000 more subscribe to the *Journal of the American Medical Association*. United effort on the part of all these would do much to wipe out the evil. He presented resolutions asking the House of Delegates to consider the matter and legislate for the evil. At the request of Dr. McCleve, of California, a supplementary resolution requesting the board of trustees to remove the advertisements of all nostrums from the *Journal of the American Medical Association* was added.

The Profession to Blame.—Dr. J. J. Walsh, of New York, said that the low standard of true feeling for medicine in the profession was to blame for the evil. In New York, where the medical education is not deficient, statistics show that over 70 per cent. of all prescriptions written contain some nostrum. Inquiry at drug stores within a month after an agent comes around to introduce a new and hitherto unheard of preparation, shows that physicians have begun to prescribe it. The good senses of the profession must be aroused to the enormity of thus selling their birthright as practitioners of medicine to the pharmaceutical quacks for even less than the proverbial mess of pottage.

State and Association Journals.—Dr. Moore, of St. Louis, said that even the State and medical association journals are not free from the objection of catering to advertisers who have secret nostrums to sell. This of course perpetuates the evil. Some one has spoken of Dr. Billings' action in attacking secret nostrums as courageous, but is it possible that members of the medical profession would actually be afraid to express opinions in this matter? Are doctors not men first?

Dr. Priestly, of Iowa, said that medical students are not taught properly to prescribe and their laxity in taking up with these ready-made prescriptions is due to this.

Dr. Strickenfeld, of Utah, said that in St. Louis it was the custom for medical students about to graduate to go around to the secret nostrum houses, of which there are so many in that city, and get a stock of these pharmacals to begin practice on. After they exhausted the supply they sometimes came back to the city to replenish their stores gratis.

Dr. Witherspoon, of Kentucky, said that the true physician is a medical student all his life. The fact that he has not learned prescription writing before graduation should only make a renewed incentive to learn it after, if he has the true professional spirit. The blame must not be laid on the medical schools but the men. Nostrum prescribing narrowed their minds until at last it was impossible for them to advance in medicine.

Dr. King, of Washington, said that an evil cannot, any more than a plant, be killed by cutting off its head. The root must be got at. Medical education must be improved from its practical side. In the postgraduate schools diagnosis, pathology, bacteriology, are all insisted on. Treatment is scarcely mentioned. Hence physicians grasp at the will-o'-the-wisp with the promise in it held out by the oily manufacturing chemist.

Dr. Grosse, of California, said that the battle against the nostrum was in full tilt in California and he is glad to see it spread. Unfortunately even reputable medical journals publish the "ads." of these nostrum venders and the unsuspicious reader cannot but think they must have some virtue in them.

Dr. McCleve, of California, said that in condemning the medical journals that of the Association itself must not be passed over in silence. It also admits what are, to say the least, objectionable "ads." to its columns.

Dr. Stockton, of Buffalo, said that publicity will be of the greatest help in this struggle with the nostrum. The fact that names are mentioned publicly, as in Dr. Billings' paper, must result in good. The more complete the exposure the more will the profession realize the fraud.

At the suggestion of Dr. Carter, of Victoria, Dr. Walsh, of New York, offered a resolution that the set of resolutions with regard to the nostrums adopted at

this session should be transmitted to the Canadian Medical Association for consideration, inviting joint action in any measures that may be adopted to mitigate the evil. The resolution as also the previous resolutions for the house of delegates and the board of trustees were passed without a dissenting voice.

Nitric Acid Fumes Inhalation.—Dr. J. N. Hall, of Colorado, read for himself and Dr. C. E. Casper, of Denver, a paper describing in detail the effect of nitric acid fumes on the lungs in some 20 cases. The patients were firemen, called to put out a fire due to the breakage of a carboy of stray nitric acid. The acid was soaked up with sawdust which oxidized very rapidly and burst into flames in many places. For this the firemen were summoned and found a thick, irritating smoke evidently due to a combination of acid fumes with the burning sawdust. The acid was very concentrated, over 38 per cent. in strength and contained no noteworthy proportion of nitrous acid and no sulphur impurities.

Course of Symptoms.—The men were overcome much more rapidly than ordinarily by smoke and there was an intense feeling of irritation of the respiratory passages on first going near the flames and then immediately after coming out from the first effects of the collapse incident to exposure to the fumes. The men were taken immediately to the hospital, but thought no more of their condition than if they had been overcome by smoke, which is a common experience with them. All of them asked and were permitted to return to their homes after a few hours. All of them, however, without exception, were brought back to the hospital within from six to twenty hours, because of severe irritative symptoms in the respiratory mucous membrane and because of the development of intense congestion of the lungs. After their return to the hospital all suffered from vomiting and some signs of collapse, and all of them complained of sharp pains on breathing as well as difficulty of respiration. All of the victims suffered from pleuritic pains, which on investigation proved to be accompanied by pleuritic friction sounds so that the pleura was evidently affected. After the signs of active congestion passed areas of consolidation could be demonstrated here and there. This bronchopneumonia proved of slow course and very prostrating in its tendency. The general symptoms did not seem to be different from those noted after the inhalation of chlorine or other irritant gases. Four of the cases proved fatal, one not long after the accident, three others toward the end of the month afterward. These three had recovered apparently from their bronchopneumonia and then suffered a fatal relapse. At autopsy the evidence of bronchopneumonia was clear.

Milwaukee Cases.—Dr. Neilsen, of Wisconsin, said that two years ago a similar accident ocurred in Milwaukee, and the symptoms ran a similar course. All of the men went to their homes after a couple of hours and then had to return later on for treatment. The signs were those of intense congestion of the lungs, though at first there seemed to be only a superficial though troublesome irritation of the respiratory mucous membrane. All of the cases improved very slowly and the return to complete health was long delayed. Finally all of them had to be sent to Texas to recuperate. On the way one of them, discouraged by the slow progress of his case, committed suicide.

Absorption of Toxic Material.—Dr. McCaskey, of Indiana, said that some of the prostration and general symptoms as well as the failure to react seemed in these cases to be due to the direct absorption of toxic material into the blood during inhalation. This should be an indication for treatment in such cases. The vomiting seems to have been nature's protective effort to throw off some of this absorbed material, which could not escape through the congested lungs.

Non-Infectious Bronchopneumonia.—Dr. J. H. Musser, of Philadelphia, said that the most interesting phase of Dr. Hall's work is undoubtedly the demonstration of the possibility of the production of bronchopneumonia by direct severe irritation. In recent years only the infectious factors in the etiology of bronchopneumonia have been considered to the exclusion of other important sources of this inflammatory reaction. It is for the careful study of this subject in recent papers that Dr. Hall is to be especially commended.

Slow Poison.—Dr. Hall, in closing the discussion, said that there were some symptoms in the cases extremely difficult to explain. The vomiting scarcely seemed to be due to poison, however, since it did not occur at once but in from twelve to twenty hours or more after the exposure; it would seem as though some broken down tissue material were being absorbed which was giving rise to the prostration and vomiting. Poison acts at once, all the men went home and then, later, had to come back to the hospital.

On motion of Dr. Musser, the paper of Drs. James E. Talley and William S. Newcomet, of Philadelphia, on "Studies in Roentgen Ray Diagnosis," with special attention to the diagnosis of pathologic conditions within the chest, was read by title.

SECOND DAY—JULY 12TH.

SYMPOSIUM ON NEPHRITIS.

General Considerations on Pathology.—Dr. W. T. Councilman, of Boston, said that the principal anomalies are chiefly those of position. The kidney is situated lower than usual or it hangs more loosely. In the normal kidney there is great differentiation of tissue and function. One curious feature of the kidney is its capacity for repair and yet the little ability it displays for perfection of regeneration. While new form tissue will frequently be found here and there, and the tendency to its formation is quite marked, complete new kidney structure does not occur in this way. With advancing age there is considerable impairment of kidney structure, mainly due to destruction and degeneration of the true secreting tissue. Hand in hand with this there goes an increase of connective tissue. The true kidney tissue usually suffers first and there is the overgrowth of connective tissue.

Bacterial Infections.—The bacterial infections of the kidneys resemble in their effects the conditions produced elsewhere by microbes. The most common group of renal diseases are those produced not by microbes directly, but by certain soluble toxic substances produced by the growth of micro-organisms or by disorders of the circulation. Interstitial changes in the kidney are practically always secondary to injuries of the true secreting substance. The most important legions of the kidney are those which affect the glomeruli. These are affected alone or principally, the inflammation may be acute, subacute or chronic. It is possible to make broad classifications on the basis of the pathological and anatomical changes. These, however, do not stand the test of clinical observation. The future study of the diseases must be along clinical and experimental lines.

Albuminuria in Nephritis.—Dr. Alfred Stengel, of Philadelphia, insisted on the necessity of distinguishing nephritis in the pathologic sense from nephritis in the chemical sense, which is the Bright's disease of ordinary conversation. Much of the chronic interstitial nephritis that is due to arterial conditions must not be considered as true Bright's disease; the

kidney symptoms are indeed a local manifestation of the arterial condition. Consequently all of these cases were eliminated by Dr. Stengel in his study of the relationship of albumin to Bright's disease. Altogether the records of 581 cases have been analyzed. Of these, 107 cases showed albuminuria, so there was no true Bright's disease. They included such conditions as diabetes, pregnancy, the albuminaria of adolescence and of the terminal stages of various affections. In these circumstances the albumin present is an expression of other diseases rather than of nephritis.

Nephritis without Albuminuria.—In over 200 cases of true nephritis there was no albumin present at any time while the patient was under observation. Eleven of these cases showed the presence of casts. The test used was that by heat and nitric acid, and all of the testing was done by one person. This test is not as delicate as some of the other tests employed, but it has the decided advantage of not reacting on other substances besides albumin, nor to such small amounts of albumin as constitute the presence of this pathological material.

Albuminuria without Bright's Disease.—This was observed in a large proportion of cases, but the albumin was never in large quantity, and, indeed, it was usually said to exist only in traces. Another prominent feature was that it was unusually fluctuating, and never permanently present. There were, however, some exception to these rules. Occasionally albumin was present in quite large quantities without apparently having any pathological significance. One young woman presented for two years the large albuminuria, the large amount of albumin was present in the morning and never at any other time. She was warned of the necessity of exercising care with regard to every detail of life. She married and was warned with regard to the dangers of pregnancy in the presence of her kidney condition. After a time she became pregnant, but her pregnancy did not seem to have any deleterious influence upon her kidney condition. No eclampsia developed and no signs of any serious nephritic complication. Her labor was without incident. She had three children altogether, and at the present time there is no trace of albuminuria. In contradistinction to this fluctuating albuminuria is the constancy and uniformity of the albumin present in Bright's disease.

Infections and Albuminuria.—Nearly all the infectious diseases are accompanied by a distinct amount of albumin in the urine. Among those noted as producing this effect were such simple infections as tonsillitis, erysipelas, acute rheumatism, gonorrheal rheumatism, and, indeed, all of infectious diseases accompanied by fever. In 290 cases of typhoid fever, 83 showed the presence of a distinct amount of albumin in the urine. It would seem as though the waste of tissue during febrile condition gave rise to substances which, passing through the kidney, irritated it sufficiently to allow the escape of albumin, or that albuminous material was somehow absorbed and then excreted.

Cardiac Disease and Albuminuria.—In practically all advanced cardiac disease albumin is present in the urine. In 154 cases in which cardiovascular changes were present, 81 had albumin, and 72 none. The urine is variable in cardiac disease in content of albumin, but this corresponds as a rule to the cardiac sufficiency. When small amounts of urine are passed and the urine is rather concentrated, considerable albumin is likely to be present. On the contrary, when cardiac sufficiency has been established and the urine has become normal in amount, then the amount of albumin usually decreases. This ratio can be observed in nearly all cases.

Secondary Syphilis and Albuminuria.—Dr. Stengel has observed in most of the cases of secondary syphilis under his care and among the records of the medical service of the University of Pennsylvania Hospital that albuminuria is quite common during secondary syphilis. He has few opportunities for observation in regard to this disease, but considers an investigation of it from this standpoint would furnish important information. He is not sure that the albuminuria present is due to the secondary syphilis itself, or whether it should not rather be attributed to the too frequent use of mercury in the disease. Certain it is that in most cases, if mercury is employed in considerable doses, it proves an irritant to the kidney, causing congestion, and leading to the presence of albumin in the urine.

Conclusions.—Dr. Stengel considers then that while in general albumin casts in the urine are signs of kidney disease, they may occur without any affection of the kidneys. There are certain inflammatory conditions of the kidneys of very passing nature, which may cause albumin to be present in considerable quantities. When albumin is present in considerable quantities and constantly, then it has a definite pathological significance. The presence of a trace of albumin has sometimes been exaggerated into a pathognomonic symptom of Bright's disease. Dr. Stengel does not wish to lessen the value of urinary examinations, but considers that they must always be supplemented by careful clinical observation of other organs throughout the body. A larger view must be taken of the affections, and especially the importance of vascular condition must be realized if there is to be any proper idea obtained of the kidney condition and its relation to the general health.

Casts in the Urine.—Dr. Charles P. Emerson, of Baltimore, discussed the subject of the significance of casts. Epithelial casts are sometimes said to be most significant. They are, if they consist, as is sometimes the case, of fragments of kidney tubules which have been broken off and are excreted in the urine. Not infrequently the lumen of these tubules can still be seen, leaving no doubt of the origin of the cast and of the serious pathological condition at work. Most so-called epithelial casts are only hyaline casts, on which are gathered a few cells with round nuclei. Some of these cells, as has been emphasized by Dr. Cabot, are not surely of renal origin. Even if one cell clung to a hyaline matrix it would be sufficient to constitute an epithelial cell. Pus casts and blood casts are also said to be of special significance, but they occur often in temporary conditions, such as after severe athletic exercise, or after unaccustomed exertion.

Showers of Casts.—In certain conditions there occur what has been described by the very picturesque term of "showers of casts," a sudden elimination in the urine of a great many casts. In diabetes the occurence of a shower of casts indicates the diabetic coma is about to assert itself. Many of these casts are of finely granular character, and sometimes there has been no preceding sign of kidney trouble. It is sometimes said that fine granular casts are a stage of nephritis subsequent to coarsely granular casts. This observation in diabetes seems, however, to disprove this. True hyaline casts are much rarer than they are reported. It requires careful adjustment of the light of the microscope to enable the observer to see them. They are almost exactly the color of the fluid, and escape observation.

Other Forms of Casts.—Waxy casts are not so infrequent as has been imagined, though their significance is not clear. When they are yellowish they look exactly as if they were composed of beeswax. The

lighter-colored ones remind the observer very much of paraffin. Fatty casts occur frequently in the nephritis due to malaria. How serious may be the significance of waxy casts may be gathered from the fact that they can be best observed in the urine of bladders abstracted post mortem. It seems not unlikely that some serious agonal condition is responsible for them toward the end of life.

Casts without Nephritis.—In 11 cases in which casts were present leading to the diagnosis of nephritis the autopsy showed only a chronic passive congestion. The autopsies were very carefully made and there was no sign of nephritis, either macroscopically or microscopically. In 23 cases in which casts were rather abundant in the urine, only cloudy swelling was found to be present post mortem. It is not as yet decided whether this represents a stage of inflammation, but certainly the kidneys in these cases could not be considered to be suffering from true nephritis.

Acute Nephritis of Casts.—Casts are most abundant in acute nephritis. In these cases epithelial blood and pus casts are most common, though after a time coarsely granular casts are found, only later do the finely granular casts occur. Acute exacerbations of chronic kidney disease presents the same picture as acute nephritis and an abundance of casts. On the other hand, in chronic nephritis casts become much rarer. In the large white kidney, representing chronic interstitial nephritis, the larger the kidney the more the casts. In the large and small red kidney of arterial sclerosis casts are rather infrequent, and are not especialy significant. Amyloid disease was present in 18 cases under observation at Johns Hopkins. Most of these presented few casts, two of them had no casts at all, though in nine cases altogether the casts were important. In two cases waxy casts were present, but very few casts showing the true amyloid reaction.

Conclusions.—Casts predominate then in acute conditions of the kidney. The better the condition of the kidney just before the irritant enters it, which causes the casts, the more casts will eventually be present. In diabetes without preliminary nephritis, there may be a shower of casts with an enormous number of them, and any diffiuse kidney condition due to irritation may produce a like effect. Athletes, especially bicyclists, foot runners and oarsmen, often have a large number of casts in their urine just after they have undergone severe exertion. The kidney seems after a time to get used to the irritant present in the system, and then the casts cease to appear. The sudden exertion produces materials which irritate the healthy kidney into a reaction that looks like a pathological condition.

Irritant Substances and Cases.—Certain foodstuffs, as asparagus, seem to have a definite tendency to give rise to casts in the urine. Most of the spices, and especially mustard, has this same effect. On the other hand, salicylic acid, even in ordinary doses in susceptible subjects, may give rise to casts. In one person under observation at Johns Hopkins Hospital, the presence of casts seemed to be a hysterical manifestation, though they have been seen at intervals for many years no serious effect has followed, and it would seem as though the condition which they represented was not distinctly degenerative nor progressive.

Puerperal Eclampsia in Relation to the Kidney.—Dr. Philip King Brown, of San Francisco, has studied the analyses of 54,000 births. In 105 of these births some symptoms of eclampsia developed. Most of them were hospital cases, hence the proportion of eclampsia is higher, for many of the patients were admitted to the hospital because of the development of eclamptic symptoms. In 18 per cent. of all these eclampsia cases true nephritis was not present, but only renal irritation. The connection between the kidney and eclampsia is by no means as clear as used to be thought, and the fact that albumin in casts frequently appear during pregnancy, does not at all necessarily signify that nephritis is developing. The strain the kidneys are undergoing resembles that which they are subjected to in the severe exertion of athletes, and so it is not surprising that casts and albumin should be present.

Contributing Factors to Eclampsia.—Dr. Brown calls attention to the fact that thyroid enlargement is quite common in pregnancy, and this seems to be due to the fact that greater calls are made on the functions of this gland, which it is sometimes not able to meet except by hypertrophy. At times sufficient thyroid substance is not prepared, and consequently an intoxication results. Dr. Brown has found that according to certain observers, if one-fifth of the thyroid glands be removed from pregnant cats, attacks develop which are not unlike those of eclampsia. As a matter of fact the only connection between the kidney and eclampsia has been the similarity of eclamptic attacks to uremic seizures.

Decrease of Urea.—Dr. Brown calls attention to the fact that the ordinary observations on the amount of urea in cases where eclampsia is threatened are not likely to be of much service. In certain quite normal cases there is a decrease of the urea toward the end of pregnancy. The present methods of estimating urea do not give sufficiently definite information. The reduction in urea excretions by no means indicates a danger signal.

Other Theories.—There are other theories as to the origin of eclampsia. The most prominent are those which associate with changes in the liver and in the placenta. In quite a few cases the changes in the liver found in eclamptic subjects have been quite as marked as those found in the kidneys. Animals with hepatic fistulæ have not infrequently suffered from an intoxication resembling uremia. Hence the supposed connection of the liver with eclampsia. With regard to the placenta, recent observations seem to show marked change in that organ in patients who have died from eclampsia. The serum of the child in eclamptic cases is hemolytic for the maternal blood. It would seem as though certain affections of the placenta might be reflected in the mother's condition. Some observers have considered eclampsia due to a general disturbance of metabolism. Just as the diacetic acid causes diabetic coma, so some as yet unknown substance in the circulation may cause eclampsia.

Muscular Irritability — Personal Observation.—Dr. Brown has found that the muscles of pregnant guinea-pigs are much more excitable than those of animals under ordinary conditions. Irritants which produce no effect at all on the muscles of non-pregnant animals will set the muscles of the pregnant animal in a state of spasmodic contraction. It would seem that this is a contributing cause to the eclamptic convulsions. The muscles of the pregnant woman are much more irritable to irritants of almost any kind, and consequently the convulsions occur.

(To be Continued.)

SECTION ON SURGERY AND ANATOMY

FIRST DAY—JULY 11TH.

Chairman's Address.—Dr. Maurice H. Richardson, of Boston, Mass., referred to some of the accidents and mistakes in surgery and gave a number of instances of errors, particularly in diagnosis, occurring to himself personally He called atten-

tion to the fact that the surgeon is blamed for everything that goes wrong in patients coming under his care, regardless of who might be responsible. He urged that all recent graduates should spend a number of years assisting prominent surgeons before branching out for themselves, being careful, however, to avoid becoming thereby such chronic students that they lost confidence in themselves.

The Cure of Hernia.—Dr. H. O. Marcy, of Boston, Mass., read this paper. In it he traced the history of the modern operation for the cure of hernia from its beginning, giving his own experiences of the use of the buried animal suture for the reconstruction of the inguinal canal through the abdominal wall, restoring it to its normal obliquity. This it was not possible to carry into effect without the use of buried sutures. As Mr. Lester's first American pupil Mr. Marcy had been taught the use of the buried animal ligature, as recommended by this great master for the occlusion of the arteries both in continuity and in amputations. It was but a logical sequence to broaden the use of the animal ligature and apply it to the reconstruction of divided structures. This was the inception of the buried animal suture and had its first application for the cure of hernia in 1870. Since 1882, when he used the kangaroo tendon suture, he has used exclusively this surgical material. Although not universally adopted, the kangaroo tendon suture is, he believes, for many reasons considered the best. The cause of inguinal hernia in the male is more commonly found in the lack of the developmental processes of infantile life. Here not seldom the structures about the internal ring are defective, permitting a direct intra-abdominal pressure resulting in hernia. The cure is found in the restoration of these parts to their normal condition. There are many modifications of the operation of minor character, the results of which are excellent, but the fundamental physiological basis of the operation must ever remain.

Fibroid Growths of the Abdominal Wall.—Dr. C. A. Powers, of Denver, Colo., referred to the infrequency of these so-called dermoid tumors, and stated that they generally occurred in women from twenty-five to thirty-five years of age, who have recently been pregnant, and most often in the region of the right rectus muscle below the naval. He considered at some length the etiology, form, size, pathology, development and course, and also the symptoms, diagnosis, management and the immediate and remote results of operations. Postoperative hernia and relapse of growth was referred to, together with a review of the literature on the subject, and of the author's cases.

Dr. R. F. Weir, of New York, reported having seen two cases similar to those referred to by Dr. Powers.

Dr. Rixford, of San Francisco, reported one similar case; Dr. McGlennon, of Baltimore, Md., reported another, as also did Dr. Connell, of Fon du Lac, Wis., who had seen two cases; Dr. Willoughby, of Los Angeles, and Dr. Fulton, of Astoria.

The Chairman referred to the effect of Dr. Coley's serum in cases such as those reported, and claimed that he had seen considerable benefit result from this treatment.

Splanchnoptosis from a Surgical Standpoint.—Dr. James E. Moore, of Minneapolis, Minn., stated that there was great confusion in the use of terms that applied to ptosis of the abdominal organs, splanchnoptosis being, probably, the best general term. Glenard, in 1885, gave the first good description of this condition, and claimed that splanchnoptosis included all of the abdominal organs and that it never occurred without serious digestive troubles. The causes of splanchnoptosis are not well understood. The symptoms vary according to the organ or organs most affected, but in a general way they are those of neurasthenia. A patient suffering from this train of symptoms should never be pronounced dyspeptic, hysteric or neurasthenic and be sent away with a prescription without having a most careful physical examination made. Hepatoptosis is much more frequently involved than we have heretofore believed, and when the liver is prolapsed all of the other organs must come with it because of their anatomical relations. Glenard said that splanchnoptosis is incurable, but he recommended medical treatment and the abdominal binder only. The fact that operations for ptosis of the various organs can be done almost without mortality gives us no license to operate indiscriminately, but it entitles these sufferers to the help of surgery. When a patient comes in consultation with this motely array of symptoms some one of the organs should not be picked out, but a thorough diagnosis and a complete operation should be made. The relative frequency and importance of ptosis of the various organs depends upon the observer's viewpoint. When the internist, the neurologist, the gynecologist and the surgeon gain the same viewpoint all will be in a position to accomplish the most good. Surgery should not be recommended in these cases until intelligent medical treatment has failed, but the latter having failed it is the surgeon's duty to operate. Surgery cannot be offered as a panacea, because there is a possibility that neurasthenia may continue after all mechanical defects have been repaired. Past failures are largely due to incomplete operations. The shortening of suspensory ligaments alone is liable to result in failure, because they were surely not intended by nature to bear the weight of these organs. Attention must be given to the support from below. It is still a moot point as to whether a prolapsed organ or neurasthenia, when found together, is the primary condition, because each of these conditions may exist without the other, but the cure of the prolapse will ofttimes cure the nervous condition. Any operation in which a direct attachment of the stomach is made to the abdominal wall is bad surgery. The application of the gastrohepatic and gastrosplenic omentum is theoretically good, but the frail tissues may not hold. After a failure from this cause the writer made an anastomosis between the prolapsed colon and the sigmoid, which resulted in a complete cure. Gastroenterostomy is the best operation for a dilated stomach when dilatation is not due to atony. Recent experiences have taught that hepatopexy is a safe and satisfactory operation. A number of mattress sutures of chromic catgut or kangaroo tendon are passed from below upward through the liver about one and a half inches from its margin, then through a good bite of the soft parts underneath the costal cartilages, then downward through the liver again so that the knots can be tied below when the liver is held in place. All sutures should be passed before any are tied. These are undesirable patients because of their extremely stormy convalescence, but the immediate prognosis is good, and, while experience as to end results is too limited to draw definite conclusions from, it is so far sufficiently encouraging to justify the belief that one may be able in future to restore to health and usefulness many who have heretofore been condemned to hopeless invalidism.

Dr. Coffey, of Portland, showed a number of illustrations, giving a very good idea of some work he had done along this line, one of the most important illustrated the various methods in which the abdominal organs are suspended.

Early Diagnosis of Gastric Ulcer.—Dr. H. D. Niles, of Salt Lake City, took up the relative frequency of the different symptoms of this affection and the various diseases resulting therefrom. He advised the grouping of these symptoms before making a positive diagnosis and deciding on exploratory incision.

Clinical Experiences With the Use of the McGraw Elastic Ligature.—Dr. A. J. Ochsner, of Chicago, described his operation, which is an elaboration of the original enclyran ligature in detail, and gave the results obtained in several cases.

Chronic Ulcer of the Stomach and First Portion of the Duodenum, with Especial Reference to Operative Treatment.—Dr. William J. Mayo, of Rochester, Minn., in this paper, stated that clinical observation as to the frequency of gastric ulcer gives from 1/12 to ½ of 1 per cent., while post-mortem examinations show 1½ per cent. in America to above 5 per cent. in Europe. Duodenal ulcer has not been closely observed either clinically or at post-mortem. At the operating table the duodenum has been found to be involved in more than one-quarter of the cases, and in more than one-half of these subjects there were no gastric complications. Of nearly 800 operations upon the stomach and duodenum in the hands of Dr. Chas. H. Mayo and the writer, nearly 450 were for ulcer or some of its numerous complications. Medical cures shown by statistics to be from 20 to 40 per cent., but like attacks of recurrent appendicitis or gall-stone colic, subsidence of acute exacerbation may not mean cure. In two and one-half years, 280 gastric and duodenal ulcers operated at St. Mary's Hospital, 231 were subjected to gastrojejunostomy, 119 males, 112 females. Of 231 cases, 60 involved the duodenum. Mortality of the last 140 gastrojejunostomies was less than 3 per cent; last 80 but one death. Two clinical groups should be distinguished. (1) Surgical or pathological ulcer, involving all coats of stomach or duodenum, and easily recognized from exterior of organ, and at least two-thirds occur in males. (2) Medical or clinical ulcer involving only mucous coat, and not indicating location without examination of interior of gastric cavity more numerous in females. Operation is not indicated in the prolapsed, dilated stomach due to the neurasthenic state, in atonic dilatation, nor in acute ulcer, unless for complication (perforation, hemorrhage, etc.). The author said he would advise and practice operation in cases with obstruction, the results of ulcer, and in cases in which prolonged medical treatment has failed to cure an active or relapsing ulcer. Gastrojejunostomy made by suture between the posterior, inferior wall of stomach and jejunum within three inches of origin (no loop) gives best results. Excision of ulcer, Finney's and Rodman's operations have an increasing field of usefulness.

Dr. Ochsner took up the question of the Finney operation and also the Moynihan operation.

Dr. Mayo also referred to the Finney operation and particularly to the interesting statistics of Dr. Francine.

Acid Intoxication and Late Poisonous Effects of Anesthetics.—Dr. A. D. Bevan, of Chicago, called particular attention to the effect of chloroform on the liver, and stated that it was a frequent cause of death some days after anesthesia, the condition being as definite a pathological entity as acute pancreatitis, or phosphorus poisoning. The changes are in many respects similar to the acute cell-poisoning induced by arsenic.

Dr. H. C. Moffitt, of San Francisco, gave the details of six cases which he believed had died from the effects of chloroform.

Dr. Woods Hutchinson, of Portland, felt that Dr. Bevan's paper would be a great aid in assisting toward the development of the newer views regarding the functions of the liver, and more particularly in their relationship to various types of suboxidative intoxications.

Perforations in Typhoid Fever.—Dr. Richard H. Harte, of Philadelphia, reported a number of cases in support of his thesis that a surgeon should always be on hand in all cases of typhoid fever; and urged that he should be called in earlier by medical men, particularly in those cases in which perforation was to be feared.

Dr. Lawrence Litchfield, of Pittsburg, asked if Dr. Harte referred to local or general anesthesia, and also as to whether or not any observations were made with a view to determining blood pressure.

Dr. Charles A. Powers, of Denver, Col., commented on the excellent results of Dr. Harte's previons work along this line.

Dr. Manges, of New York, called attention to the importance of a fall in the temperature and an increase in perspiration as diagnostic features of the occurrence of perforation.

The author replied to Dr. Litchfield's inquiries by stating that he referred to general anesthesia, and that he had had no experience on the question of blood pressure.

SECOND DAY—JULY 12TH.

A Clinical Chart for the Record of Patients in Small Hospitals.—Dr. George F. Wilson, of Portland, Ore., read this paper, and stated that on account of the scarcity of clerical help in the small hospitals throughout our country no record of scientific work is preserved. A simple form of chart, prepared as such, without the necessity of being copied into record books, offered for suggestions and improvements, that such work could be preserved in an accessible form.

Dr. Wright, of Salt Lake City, considered the chart was too large, and that the spacing was not satisfactory.

Dr. Harry M. Sherman, of San Francisco, objected to the necessity of writing on both sides and to the fact that the chart was to be kept by some one other than the physician himself.

Preliminary Report of a Statistical Study of Tetanus.—Dr. James M. Anders and Dr. Arthur C. Morgan, of Philadelphia, read a paper on this subject. They undertook a study of the literature from 1850 to 1904, covering the reports of cases found in the Index-Catalogue of the Library of the Surgeon-General, in Washington, from 1850 to 1892, and the Index Medicus from 1892 to 1904 inclusive, or 949 cases, with a report of 252 original cases collected by themselves from direct correspondence with hundreds of observers all over the country, giving a total of 1,201 cases. These collective investigations afford convincing proof that in every case of the disease the tetanus bacillus is introduced into the body through a lesion of the skin. Their observations concerning the distribution and prevalence of tetanus in the United States gave rather misleading results, and hence they adduced tabulated reports from the Census Statistics of the United States, ex-

tending over a period of thirty years. The figures are impressive as showing the appalling mortality from tetanus of the newborn. Their statistics showed that while Fourth of July tetanus is vastly on the increase, in general the disease has been on the decrease as compared with the population. They found out that there is a strip of land, extending from the village of Oceanic, New Jersey, on the east, to the west of Red Bank, on the west, the said strip being about one mile wide and five miles long, where tetanus is strongly endemic. The incidence of the disease is influenced by the seasons, and while Fourth of July is on the increase, independently of this fact,, the statement holds true that tetanus is more prevalent in the hotter as compared with the colder months of the year. The cases were tabulated with reference to the age; the disease is most frequent in the young, or before the twenty-fifth year. Males made up 79.3 per cent. of 981 cases in which the sex was noted. An interesting table, showing the infection areas, was presented; it showed that the extremities, notably the hands and feet, are the most common sites of infection. There is evidence to show that tetanus is directly transmissible. In their tabulated cases, several interesting clinical features were brought to light. In one case the trismus was so great that the teeth were crushed down to their roots, and in another the spinal processes of the vertebræ were fractured by the severity of the convulsions. Leucocytosis was noted in one instance, and it was thought that this symptom might be more common than is generally supposed. In one case the patient had a temperature of 1° F. every day during the period of incubation, and the writers suggest the importance of recording the temperature in suspicious cases, in order to determine whether there is any connection between a slight febrile movement and tetanus. In three cases the first symptom noticed was pain referred to the diaphragm; in another the diagnosis of hydrophobia was maintained for several days. In nearly all cases in which serum was injected cutaneous rashes, more especially urticaria and erythema, were noted. Their studies indicate the high diagnostic importance of the constancy of the tonic contractions in tetanus, since in other conditions, which simulate this disease, as hysteria, uremia, and strychnine poisoning, the contractions are intermittent. A table showing the incubation period and its relation to the mortality-rate embraced some interesting points. It was especially observed that the cases showing a short incubation period gave a high mortality-rate, while those that developed late, (*e.g.*, after the fifteenth day), gave a much lower death-rate. Another tabulation indicated the duration and its relation to the death-rate. No new facts were developed with reference to the treatment. There is uniform agreement that the immediate radical treatment of all wounds, followed by the local use of the dried serum, and this in turn by prophylactic injections of the antitoxin, preferably subcutaneously, is the best known method of treatment. Finally, in fully developed cases of tetanus, antitoxin does not have any appreciable beneficial effect.

Dr. L. L. McArthur, of Chicago, called attention to the importance of the early diagnosis of cases of tetanus, and said that in Chicago it had been the custom to administer antitoxin to patients in whom tetanus was likely to develop before receiving the report of the bacteriologist of the positive findings of the organism.

Dr. McCaskey, of Fort Wayne, Ind., objected to the method of serum injection before a positive diagnosis had been made, and felt that the thorough cleansing of the wound was all that was necessary.

Dr. Walsh, of Erie, reported a case of death from tetanus, although thoroughly treated by him within an hour of the accident.

Dr. Anders closed the discussion by arguing in favor of prophylactic treatment.

Cysts of the Spleen.—Dr. W. A. Bryan, of Nashville, Tenn., read this paper, and said cysts of the spleen rarely occurred without similar lesions elsewhere. They are classified as (1) dermoid, one case reported by Andral; (2) simple, serous, or blood cysts; (3) echinococcus cysts. He stated that cyst walls were fibrous tissue with more or less unstriped muscle fibers, with or without endothelial lining. The contents varied with the type of cyst. Small cysts produced no symptoms. Large cysts, he stated, produced symptoms of their size and weight. Begun in left hypochondrium, movable unless adhered, fluctuant, pain in left hypochondrium, epigastrium and left subscapular region. Nausea and vomiting might occur and rarely obstructive symptoms. Hydatid thrill absent in 50 per cent. of echinococcus, and found at times in ascites and ovarian cysts. Splenic cysts must be differentiated from abscess of spleen, ovarian cysts, growths of the pancreas, hydronephrosis, mesenteric cysts, and enlargement of the spleen from malaria and leucemia. The history, the point of origin, direction of growth, the rate of uniformity of growth, or its absence, together with collateral symptoms and signs now and then make a diagnosis possible. Cyst of a wandering spleen would present great difficulty of diagnosis.

The terminations of cysts of the spleen are by absorption, abscess formation, rupture into a viscus, or into the pleura or abdominal cavity, where the fluid is capable of producing numerous cysts of the peritoneum echinococcus.

The treatment is to open and drain or do splenectomy. Do not excise part of spleen; do not aspirate.

Indications for the Removal of the Pathologic Spleen.—Dr. B. D. Davis, of Omaha, reviewed the recent physiology of the spleen; the several pathologic conditions suitable for splenectomy; splenic anemia, malarial spleen, sarcoma; tuberculosis and abscess. He reported a case of successful splenectomy, and gave the clinical blood and pathologic findings.

Dr. Charles A. Powers, of Denver, had operated on several cases of cyst of the spleen and had been fortunate in having little or no bad results; whereas diagnosis was difficult, operations were not.

Dr. H. G. Marxmiller, of Cincinnati, considered that the subject should be divided into the medical and the surgical spleens, and advised the examination of a dried specimen of blood before operating.

Drs. McDonald, of San Antonio; Jepson, of Iowa; Griffith, of Kansas City, and others, reported histories of cases.

Dr. Davis closed by calling attention to the blood variations before and after operation.

Lip Operation for Cancer and Deformity, with Report of Cases.—Dr. W. W. Grant, of Denver, Col., described in detail a new operation for carcinoma of the lips and deformity of the mouth, which he claimed was superior to the ordinary operations for these conditions.

Cervical Esophagectomy: Report of a Case with Prothetic Appliances.—Dr. Wallace I. Terry, of San Francisco, Cal., in this paper claimed that the involvement of the cervical portion of the esophagus

was secondary to the epithelioma of the larynx. He reported having done a previous laryngectomy with resection of the esophagus and removal of the submaxillary glands, epiglottis and thyroid gland, and described the technic of the operation and the prothetic appliances for feeding and phonation.

Cancer.—Dr. William L. Rodman, of Philadelphia, considered that cancer was increasing in frequency; that the parasitic theory has not been proven; that the weight of evidence was against it, and that prolonged irritation was seemingly the most reasonable cause. The general belief that benign growths frequently undergo cancerous change, if we excepted superficial warts and moles, he claimed could not be proven, as it was of infrequent occurrence, while sarcomatous change was more frequent. He stated that prognosis varied with the varicty of growth, age of patient, etc., and that diagnosis should be made as early as possible, supplementing the ordinary clinical means by microscope if necessary. The only safe treatment, in his opinion, consisted in free and early excision. Whereas, superficial squamous epitheliomata may be treated successfully by caustic and X-rays, other varieties were more often made worse instead of better by such treatment. Where it could be shown that a precancerous stage existed, operation should be done at once, but it was at first necessary to show that it existed, and impressions should not be accepted as facts.

Dr. Levings, of Milwaukee, called attention to the apparent relation existing between tuberculosis and cancer and gave instances of families where this seemed to have been proven.

Dr. Jacob Frank, of Chicago, mentioned a case similar to Dr. Terry's, on whom he had operated for carcinoma of the larynx, and in whom the remarkable result was obtained of the patient being able to articulate loud enough to be heard by everybody in a room with a seating capacity of three hundred.

New Method of Incising and Suturing the Liver to Re-establish Its Continuity, and for the Control of Hemorrhage.—Dr. Jacob Frank, of Chicago, described his method of operating, particularly in the controlling of the hemorrhage. He stated that his chief object was to bring his flaps together, and obliterate all dead space, as this re-established the continuity of the liver surface, and left no raw surface nor ragged edge.

Gall-Stones in the Common Duct.—Dr. W. D. Haggard, of Nashville, Tenn., mentioned a number of cases on which he had operated, and looked upon stones in the feces as an indication for operation. He considered that operation in the presence of prolonged jaundice was dangerous, and mentioned a number of differential points between tumor and stone obstruction.

Non-Calculous Cholecystitis.—Dr. Davis S. Fairchild, of Des Moines, Iowa, called attention to the number of cases operated upon for gall-stones where no stones were found. In addition, he mentioned that practically no changes were sometimes observed in the appearance of the gall-bladder, in spite of the supposed gall-bladder disease.

Dr. McLaren, of Minneapolis, said that hemorrhage following operation for gall-stones was not always to be feared, although it possibly should never be forgotten. He believed, further, that the presence of stones in the feces indicated that they were almost always associated with stones in the common duct.

Dr. Porter, of Fort Wayne, Ind., reported a history showing that the patient had been well for ten years following an attack of gall-stone colic. He finally came to operation for the relief of biliary obstruction.

Dr. A. J. Ochsner, of Chicago, called attention to the important points in Dr. Frank's paper: (1) the importance of making distinct flaps; (2) the clean surface, and (3) the care required in closing the liver wound. He said that acute obstruction of the common duct was no longer operated hastily as in times gone by, and he thought of late greater success had attended the operation as a result.

Dr. William J. Mayo, of Rochester, Minn., spoke in favor of Dr. Frank's method of controlling hemorrhage in liver surgery, and added that the injection of hot water into the liver was very beneficial for the same purpose. He urged the necessity of carefully differentiating one's gall-bladder cases, and said that one could never be sure a case of gall-bladder was going to do well. He spoke concerning the very irregular relation between jaundice and pain. Jaundice in particular often being very variable in intensity, or even in its actual occurrence.

Dr. J. J. Hamilton, of Idaho, reported an interesting case of gall-bladder disease. The patient operated upon himself without an anesthetic, removed six stones, and made a good recovery.

Dr. Frank, in closing, believed it was possible to readily control hemorrhage and liver operations, and urged that liver surgery should be put on a plane with appendicitis.

Dr. Haggard closed by stating that he was always dubious about accepting the statement of a patient that they had passed gall-stones unless they could produce them.

(To be Continued.)

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JULY 11TH.

The Teaching of Pediatrics.—Dr. John Lovett Morse, of Boston, the Chairman, began his address with a general description of the methods of teaching now in use in the Harvard Medical School. In brief these consist of lectures and laboratory work, on the now well-known concentration plan, during the first two years, the addition of the basal facts in the practical aspects of medicine with preliminary clinical work in the third year, and a fourth year of clinical work on the Elective System. In the fourth year, as well as in the clinical work of the third year, the students are divided into sections so that an average of about one instruction to every four or five students exists. The Pediatric Department controls the material in the Children's and Infants' Hospitals, and in the Infectious Department of the Boston City Hospital. The instruction in the third year consists of lectures, clinical lectures and instruction in case taking. The instruction does not always cover the same ground from year to year, but certain subjects of supreme importance, as diseases of the digestive system and the heart and lungs, are always taken up. The system of case taking consists in presenting to the students a variety of typewritten descriptions of actual cases which he is required to read up and diagnose. The students of the fourth year take one or more courses in pediatrics, lasting a month each, during which each student assists in the ward work, studies special cases or groups of cases and is encouraged to do original work. Postgraduate courses are given at certain times of the year. Dr. Morse emphasized the necessity of making pediatrics a special department, independent, and taught by specialists; only under such a system can the specialty be adequately taught. He also empha-

sized the necessity of leaving the clinical work of the third year to the end of the year and devoting the beginning to grounding the student in the anatomy, physiology and pathology of childhood. He suggested that there is still room for the didactic lecture if this is not merely the repetition of a textbook, and also that the amphitheater clinic was useful for presenting those diseases which are externally obvious. The recitation method, he stated, has been of little value in his hands. The necessity of endowing teaching positions was emphasized.

A Plea for National and Local Boards of School Hygiene.—Dr. Alice M. Smith, of Tacoma, made an appeal for a great extension of the present methods of medical school inspection. She suggested that the American Medical Association should take measures to establish national, State and local boards of school hygiene, with specially prepared physicians in charge. After commenting on the preventability of certain diseases, the financial loss from deaths, and the prevalent diseases due to faulty school hygiene, Dr. Smith outlined her plan for the prevention of the present conditions. Most of the existing bad conditions were ascribed to the ignorance of school boards, and of parents and the children themselves. Dr. Smith suggested as a remedy the formation of a national board having charge of the school hygiene and composed of non-partisan physicians, this board to cooperate with and instruct subsidiary State and local boards. The functions of the national board would be to provide plans for sanitary school buildings and school furnishings, to conduct civil service examinations for school physicians and janitors, and to publish leaflets of instruction from time to time. The State boards should have the power to choose proper sites for schools, to frame laws governing school hygiene and enforce them, to close unsanitary school buildings, to control the exclusion of degenerate or criminal children from the common schools and to keep records of the progress and development of the school children of the State.

The local boards should consist of business men and physicians, should keep records, and should confer with the national and State boards from time to time. It was proposed that in each school every child should submit to a complete physical examination, even including blood and other microscopical examinations and psychological records. The use of the Bertillon system was recommended. The records thus obtained were to be available to the State and national boards for study and reference. There was to be a county medical superintendent for the country districts, and the superintendent in each city school was to be a physician. The functions of the board were to include the distribution of literature bearing on school and general hygiene and advice to the parents of each child, based on its examination.

Dr. A. W. Fairbanks, of Boston, in the discussion, pointed out the weakness of the present system, which gives no preventive power to the Medical Inspector, and allows of little time except for the identification of already developed diseases. The same speaker characterized Dr. Smith's scheme as Utopian under present conditions, on account of the expense required, as a great increase in physicians would be demanded. The desirability of an extension of the present system was conceded by all who discussed the paper.

Rules for the Care of Young Infants in Public Institutions.—Dr. H. H. McClanahan, of Omaha, Neb., in his paper gave in a concise way his experience of over four years with an institution for the care of infants. The main points which were emphasized were the necessity for trained nurses in such institutions and a greater control over the nursing staff by the visiting physician. On the side of the infants a large amount of cubic air space, a good milk supply, and careful disinfection of napkins was insisted on. Regarding the latter matter the opinion was expressed, both in the paper and in the discussion, that careful hand disinfection after changing infants, and immediate disinfection of napkins, was of great importance in preventing the spread of diarrheal diseases. The isolation of infants who showed any signs of sickness was also insisted upon. Dr. Fairbanks, of Boston, in the discussion, suggested that the exclusion of flies from sick children was also a factor in preventing the spread of infection.

Second Day—July 12th.

Amaurotic Family Idiocy.—Dr. A. C. Cotton, of Chicago, said: This condition is often overlooked by pediatrists, as the eye conditions often predominate, though, on the other hand, the examination of the fundus is necessary for diagnosis. The name Amaurotic Family Idiocy was suggested by Sachs, who gave the first satisfactory description of the disease. The disease is a fatal one, as a rule, beginning in the first few months of infancy in children born without any apparent abnormality. Death usually occurs within the first two years, though it may be deferred. Syphilis and consanguinity do not seem to be etiological factors. The racial factor is a strong one, all of the 54 cases reported, except six, having occurred in Hebrews. Often more than one child in the family is attacked, though others may escape. In a typical case the child first manifests symptoms at about the third month, there is muscular enfeeblement and gradual loss of sight. The ocular changes are very characteristic and consist of a nebulous whitish zone about the macula. As the case progresses the strength is gradually lost, there is some emaciation, hyperacuity of hearing, and mental symptoms in the form of general lack of mental development, and attacks of explosive laughter. The child presents great hypersensitiveness, and convulsions may be caused by very slight peripheral insults, such as blowing on the face. If repeated the insults have a lessened effect, but marked reactions follows on short periods of rest. Nystagmus is quite frequently seen. The reflexes may be either increased or decreased. The cases finally show a general spastic or flaccid paralysis. Deglutition is quite frequently affected. The condition may be confused with rachitic pseudoparalysis or with spastic paraplegia, associated with congenital blindness. Dr. Cotton's paper was based on three cases personally observed and an extensive review of the literature. It was brought out in the discussion by Dr. Cotton that nearly all the cases are breast fed, and he showed that in one mother having both normal and idiotic children, the milk was normal during lactation while the healthy children were nursed, but deficient in fat while amaurotic children were nursed. Dr. Cotton was able to prolong the course of one case by adding fats to the diet. He suggested that the poverty of fat indirectly influenced the production of lecithin, which is so important in the development of the nervous system.

Ataxia of Central Origin Appearing in Childhood.—Dr. A. W. Fairbanks, of Boston, in this paper discussed the so-called heriditary cerebellar ataxia, a race condition simulating in many ways Friedreich's

ataxia. The clinical picture begins in childhood with an incoordination affecting first the legs and later involving the arms and perhaps the ocular muscles. The progress is slow. Speech may be affected and is of a peculiar character, not scanning, but suggesting that the individual thinks out each word carefully before pronouncing it. Explosive speech is at times observed. Nystagmus is usually present, and choreiform or pseudo-athetoid movements are frequently seen. The choreiform movements may be associated with movements elsewhere in the body. Lateral curvature develops rather late in the disease, and is associated with paralysis, muscle spasm and contractures. The mentality is unaffected in some cases, though others show degeneration of the mental powers and epileptiform seizures. Less common symptoms are vertigo, headache, a vacant expression, optic atrophy, ocular pareses, and attacks of unprovoked laughter. In general the disease resembles Friedreich's ataxia, but there are points of difference. The general symptoms of the disease appear later, and when they occur may mask the earlier ones. The question of tendon reflexes, which has led to great discussion, depends on the duration and extent of the disease. Taken alone they are of no value. The anatomical lesions consist in an atrophy of the noble elements in the cord and cerebellum, and an increase of the glia in the affected areas. The regions most affected in the cord are the columns of Goll and Burdoch, Clarke's column, and the pyramidal tracts, especially the crossed pyramidal tracts. The direct cerebellar tracts are also involved, probably secondarily, as the result of the changes in Clarke's column. It is to be noted that the cord columns most affected are those last developed, and it is suggested that the process supervenes on a hereditary developmental insufficiency of the affected areas.

The Prevention of Summer Diarrhea.—Dr. Maurice Ostheimer, of Philadelphia, explains the prevalence of diarrhea in summer by the action of the heat, which reduces infantile resistance and promotes the multiplication of bacteria in milk. After outlining the general care of the infant during this period, the necessity of open air, cool clothes, cleanliness, properly cared for milk and proper intervals of feeding, the author gave in detail the contents of a leaflet to be distributed to mothers and physicians. He suggested instruction in the schools, especially the high schools, of matters relating to infant hygiene, and also proposed that the milk commissioners, now present in several cities, should be increased in number. He voiced the idea that a model dairy, under the city government, and a milk modifying plant which would sell to the poor at cost should be established in every city. He condemned wholesale Pasteurizing, as the number of bacteria in milk actually increase under this treatment; he pointed out that home Pasteurizing did not have this effect. The remainder of his paper, dealing with the details to be brought out by his educational pamphlet, does not lend itself to abstracting, but should serve as a model for those interested in promulgating such methods.

A Study of Fifteen Cases of Diarrhea in Children.—Dr. John C. Cook, of Chicago. The material studied by Dr. Cook consisted of the diarrhea cases observed at the Jackson Park Sanitarium, Chicago, during the summer of 1904. Of the fifteen cases, eleven were mild and four fatal. The symptomatology was the usual one, fever ranging from 99 to 105 degrees Fahr., vomiting and diarrhea. The fatal cases showed mixed infections, as would be expected, and the pneumococcus was mainly involved. In the discussion Dr. Michael, of Chicago, stated that of 119 cases recently studied in that city, 80 cases showed the Flexner-Harris type of *Bacillus dysenteriæ*. Clinically the cases could be divided into those with predominantly toxic symptoms and those with local symptoms of ileocolitis and mucus and blood in the stools. The *Bacillus dysenteriæ* was isolated from both classes of cases, especially the ileocolitis, but some cases of ileocolitis did not show *Bacillus dysenteriæ*. Dr. Cook, in the discussion, called attention to the fact that both vomiting and the passage of feces were especially apt to occur when the fever was at its height.

Typhoid Fever in Children.—Dr. William J. Butler, of Chicago, read his paper in abstract, on account of its length. After reviewing the historical aspects of typhoid fever in children, the author summarized the results of his study of 210 cases. The usual description of the disease in children was given, and several points were emphasized. The writer's cases seemed to show a relation between vomiting and hemorrhage, especially in cases in which vomiting existed from the first was hemorrhage apt to occur. The appearance of the stools in very young children was not so characteristic as in adults, though in older children pea soup stools often occurred. A preliminary constipation was shown to have no evil significance, as has sometimes been claimed. Rose spots occurred in 54 per cent. of all cases, and herpes in three cases, though two of these had complications. The average duration of the fever was 17 1-3 days, a much shorter period than is usual in the adult. The usual parallelism between the pulse and the temperature was not present in very young children. The characteristic leucopenia was present and the Widal occurred in nearly all cases where it was tried sufficiently after. Relapses were more frequent than in adults, especially in girls. The mortality in his cases was 5.2 per cent., and was twice as frequent in relapses as in original attacks.

Pneumonia in the Young.—Dr. Edward F. Wells, of Chicago, based his paper on an analysis of 30,025 cases and 225,642 deaths, collected from his own services and the literature. The paper was partly statistical, and this portion did not lend itself to abstract. It was shown that pneumonia occurs most frequently in early childhood, less frequently from ten to thirty, and oftener from thirty to fifty-six. The mortality of the disease, however, is only moderate in early childhood, reaches its lowest level between the ages of ten to twenty years, gradually advances between twenty and fifty years, and then rapidly rises. Children may have the disease at any age, though the new born are least liable. Newly born children have no pneumococci in the throat, and do not contract pneumonia until after they acquire them. The usual clinical picture of pneumonia in children was painted, and stress laid on the difficulty of detecting the physical signs. A good deal of stress was laid on the percussion dullness, the diminished breathing and the crepitant râles. Friction was said to be infrequent, and the unusual location of the early dulness emphasized. Dr. Wells believed that the mortality is much lower than is usually stated. The treatment of the disease he considers an art. There is no specific. The treatment he recommended was common sense,

fresh air or oxygen if necessary, the avoidance of exhaustion, tepid sponge baths, followed by alcohol rubs, the free administration of water, and good nursing. Medicinally a reliable tincture of digitalis was recommended early in the disease, with caffeine or adrenalin as indicated. In the discussion which followed Dr. Cotton, of Chicago, advocated the introduction of normal salt solutions by hypodermoclysis, enteroclysis or intravenous injection. Dr. Wells opposed any but very careful use of this method, on account of the absence of reliable data concerning the action of chloride of sodium and the danger of an excess of fluid throwing too much work on the right heart. Dr. Morse emphasized the difference between the infant and the child in pneumonia, the disease being frequently fatal in the former and usually mild in the latter. He also spoke of the frequency of abdominal pain, the importance of fresh air, and emphasized Dr. Wells' caution as to the use of salt solution.

Pleural Effusions in Children.—Dr. C. F. Wahrer, of Fort Madison, Ia., read a practical, commonsense paper, emphasizing certain points in connection with pleural effusions. He commented on the fact that it was frequently overlooked, generally on account of insufficient examination. Often is it wrongly diagnosed pneumonia; nine-tenths of all cases of pleural effusion in children are due to pneumonia. The effusion is usually prevalent in children under three, and such cases, the untreated cases, usually die, and the properly treated usually recover. Dr. Wahrer emphasized the necessity for early diagnosis and early surgical intervention. Aspiration is often sufficient to effect a cure in serious cases, but in purulent effusions evacuation by the knife is necessary. This can be done in ordinary cases by any general practitioner.

The After-Effects of Diphtheria on the Heart.—This was the paper of Dr. Franklin H. White, of Boston, Mass., and was read by the Secretary, Dr. Snyder. Dr. White stated that while the effects of diphtheria on the heart and its nerves during the disease was well known, the after-effects on this organ were less well known. While moderate disturbances were common, severe ones were relatively uncommon. The cases studied to form the basis of the paper consisted of 78 individuals who had been treated during the attack at the Infectious Department of the Boston City Hospital. The cases were followed for from five months to a year after they left the hospital. Excluding babies, one-third of the cases which left the hospital had at their exit rapidity of the heart's action (100 to 120), one-third had irregularity of the heart, and a considerable number had heart murmurs. Only those in which the heart was known to be unaffected previous to the disease were considered. It was found that 90 per cent. of diphtheria cases have some cardiac trouble. The most common lesions are irregularity, rapidity, hypertrophy or valve insufficiency. Most of these cases gradually recover; the recovery occupying on an average four months' time. Some clear up after six months or even after a year. A fair number prove to be permanent. As a rule those patients who have had the severest attacks of pneumonia recover most slowly. The cardiac signs generally develop in the first or second week of the disease. Mild cases require a week's rest in hospital after the attack. More severe ones two weeks and the severest three weeks. In general the cases show no marked signs of heart disease, often only some palpitation and dyspnea after exercise. Often murmurs develop after discharge from overdoing by the patient. The murmur commonly heard is a mitral systolic, often transmitted to the axilla, associated in many cases with an accentuated pulmonic sound and hypertrophy of the heart. The author regarded some of these cases as purely functional, some as instances of relative mitral insufficiency from dilatation, and a few as true endocarditis. Some cases show pallor, weakness, rapid pulse and palpitation. Many of the cases clear up rapidly but seven per cent. still showed signs after many months. The author lays stress on the treatment of rest in bed, the length of time depending on the character of the case, tonics and the avoidance, after the patient is up, of overexertion. Even mild cases should be carefully watched. In the discussion it was generally conceded that since the antitoxin treatment of diphtheria heart complications are more common, but it was emphasized that this was not due to the antitoxin.

Dr. Fairbanks, of Boston, suggested that this fact was due to the recovery under antitoxin of many severe cases, which would have died before antitoxin days. He also emphasized the value of Schott methods in these cases.

The Management of Children with Typhoid Fever.—Dr. W. C. Hollopeter, of Philadelphia, said that a subtitle might be "A Plea for Enteroclysis." He pointed out that early diagnosis of this disease in children was difficult on account of its atypical character. It might be confounded with enteritis, pneumonia, meningitis, or auto-intoxication. The diagnosis could seldom be made before the end of the first week and the Widal and diazo tests are of little value before this time. There is no specific treatment. The indications are to reduce the toxemia and control the temperature. The patient should be in a large room with plenty of fresh air, there should be a preliminary dose of calomel and the colon should be irrigated daily. The enteroclysis both removes toxins and lowers temperature. A tepid sponge bath should be given night and morning, and the hygiene of the nose and mouth is important. The diet suggested was peptonized milk alternating with albumin water. The peptonized milk is rendered more palatable by adding carbonated water. Orange and lemon juice should be given. Water to be given freely was also advocated. Recumbency and liquid diet are necessary for ten days after convalescence. The ice cap to the head and hot water bottle to the feet were recommended in hemorrhage and cold or ice enemata.

Report of a Case of Imperforate Rectum, with Absence of Anus.—Paper read by Dr. Edward H. Small, of Pittsburg, Pa. The case reported by him was a fifth child, born in the R.O.A. position and besides the absence of anus, had a phimosis, and webbing of the second and third toes on each foot. There was also a sacral dimple. The site of the anus was punctured with a trocar one-fifth inch in diameter and this was introduced along the normal course of the rectum until a sudden lack of resistance showed entrance into the bowel. This was two inches from the perineum. Meconium flowed and the bowel was washed out. Digital dilatation revealed the rectum which was firmly attached laterally. Subsequently the case was treated by daily bowel washing, digital dilatation for eleven days and later catheter dilatation. This treatment was continued for two months, at the end of which time the rectum had descended nearly to the anus and there was a good sphincter higher up than normal. The author expresses pleasure at his success in this case but would in future employ the open method as the use of the trocar is dangerous. The peritoneum may be punctured and fatal peritonitis result.

ORIGINAL ARTICLES.

THE BACTERIAL CONTENT OF THE RAILWAY COACH.[1]

BY J. J. KINYOUN, M.D., PH.D.,
OF GLENOLDEN, PA.

DURING the year of 1896, while the writer was in charge of the Hygienic Laboratory of the Marine Hospital Service, certain experiments were made with a view of determining the value of formaldehyde gas as a disinfecting agent for the railway coach. Results were soon so promising that it was determined to make a thorough trial of this agent in a practical way to see whether it could not supplant the methods then in vogue, as these were far from being satisfactory, these methods always resulting in damaging or destroying the interior of the coach so that a complete overhauling and refurnishing was the rule. This was, of course, a very expensive procedure, and it was to be expected that the railway companies would oppose such disinfection. As a result disinfection was not resorted to as often as it would have been otherwise.

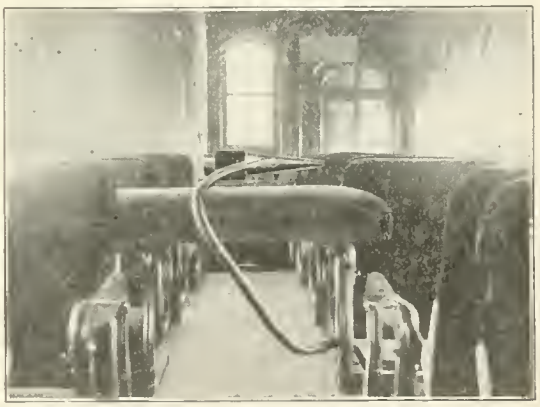
The above inquiry naturally led to an examination of the bacterial content of the railway coach. Accordingly communications were sent to the several railway companies whose lines centered in Washington, and subsequently to other lines, requesting their cooperation and assistance covering these points. All facilities for these examinations were freely granted, not only at Washington, but at many other places as well.

In view of the fact that it was a growing belief that the railway coach was one of the chief agencies in disseminating tuberculosis, it was deemed advisable to make this the prominent feature of the inquiry, and determine this first as a preliminary to a more comprehensive study. When this investigation was begun it was the intention to continue the observations over a sufficient length of time in order to include as many of the conditions as possible which affect the sanitary condition of the passenger traffic, but many lapses occurred which were unavoidable. These were chiefly due to other official duties, and on account of this many of the samples collected were not examined. These should have been included so as to make the report more complete. These unavoidable interruptions also caused the inquiry to be continued over a longer period than would have been otherwise, but notwithstanding these, it is believed that the observations so far as made are fairly representative of the sanitary conditions found in the railway coach at the time the examinations were made.

The examination included: (1) The bacterial content of dust from carpets; (2) the bacteria obtained from the interior furnishing of the coach; (3) the bacterial content of the air of the coach; (4) the bacteria of the drinking cup; (5) methods of cleansing the railway coach; (6) observations on the health of employees.

Bacterial Content of Carpet Dust.—Samples of dust from the carpets were collected usually at the cleaning stations where they were removed from the cars for the purpose of cleaning. In a few instances dust was collected from the carpet in the coach just after sweeping. The method of collecting such samples was as follows: A special apparatus with an anemometer attached was placed in the car or room near to where the carpet was either being swept or cleansed by

Fig. 1.



Showing apparatus arranged for collecting dust from carpets, etc., in the interior of car.

beating or compressed air, a certain number of cubic feet of such dust-laden air was aspirated through the apparatus, so that the dust was caught on sterilized glass wool, in such an apparatus as is shown (Fig. 1). This was then placed in a sterile container, taken to the laboratory for examination. The amount of air aspirated through the sterilized glass wool was on an average of 200 cubic feet. Some of these naturally contained more dust than others, depending upon the filthiness of the carpet. Most of these samples were collected at the terminal stations because of the superior facilities existing there for collecting them. Seven samples of such dust were collected from November, 1896, to February 28, 1898. All of these were from Pullman cars. Three of these had just returned from a trip to the South, one from Tampa, Fla.; one from Jacksonville, Fla.; one from Nashville,

[1] Read before the Section of Hygienic and Sanitary Science, of the American Medical Association, at its meeting at Atlantic City, 1904.

Tenn. (via Asheville); one from Cincinnati, Ohio; one from St. Louis, Mo., and two from Buffalo, N. Y.

As soon as possible after collection, the containers containing the samples of dust were treated with a given amount of sterilized water, and a suspension of the dust obtained. This was centrifugalized for five minutes to remove the larger particles of coal dust, sand, etc., and then afterward again centrifugalized for sedimenting the finer particles for a microscopical examination and for animal inoculations. The microscopical examination made of the dust of these samples showed a variety of substances; particles of coal, sand, vegetable fiber, epithelial cells, yeasts, molds, bacilli and cocci. Five c.c. to 10 c.c. of this precipitate was injected subcutaneously in the axilla of guinea-pigs. Two pigs were used for each experiment. A careful examination of many stained specimens from each sample for the tubercle bacillus was always negative. The number of bacteria per cubic foot ranged from 2,800 to 20,000 and over. These were of many varieties, but principally those observed in the air. Only a few pathogenic forms were encountered: the pneumococcus, *Staphylococcus pyogenes aureus*, streptococcus and the colon bacillus. Only the pneumococcus thus isolated was pathogenic, and this slightly so.

The results of the animal inoculations for these samples of dust, were as follows:

Sample from car 1, caused a pneumococcal infection.

Sample from car 2, one pig died of an acute abscess, from which the staphylococcus was isolated; the other pig was dead at the end of two months from a progressive emaciation, negative.

Sample from car 3, caused a staphylococcal infection.

Sample from car 4, negative at the end of four months. Animals gained in weight.

Sample from car 5, one pig dead from a septicemia at the end of two months (probably an intercurrent infection).

Sample from car 6, negative at the end of six months.

Sample from car 7, caused an acute staphylococcal infection in one animal, another negative after seven months.

Dust from the Interior Surfaces of the Railway Coach.—Samples of dust and other material were collected from the surfaces of the seats, bedding, curtains and woodwork by means of a swab. This swab was made of absorbent cotton firmly attached to a stiff bronze wire, and moistened with a 5 per cent. solution of glycerin, placed in a large test tube and sterilized just before being used. These swabs were rubbed over the surfaces of the seats, woodwork, bedding, etc., where it was thought possible for the tubercle bacillus to have lodged. Not less than 15 square feet was thus treated, usually as much as that contained in a section of the sleeping car, was the rule.

Samples were examined at the laboratory as soon as possible after collection. The methods employed were, each swab was transferred to a flask containing 100 c.c. of sterilized distilled water and allowed to soak therein for several hours, being occasionally agitated, after which the water was expressed and the resulting suspension centrifugalized, the sediment collected for microscopical examination and for animal inoculations.

A microscopical examination of these samples showed them to contain various bacteria, epithelial and pus cells, coal, sand, vegetable fiber, hair and feathers. Numerous specimens from samples were also stained and examined for the tubercle bacillus, and in two instances bacilli resembling morphologically and tinctorially the tubercle bacillus. There seemed to be but little doubt as to these being tubercle bacilli because they were not decolorized by strong nitric acid and alcohol, although this was not verified by animal inoculations.

Thirty-four railway coaches were examined in this manner, 29 Pullman sleeping cars, 3 day coaches, and 2 smoking cars. These cars were not confined to any one part of the country, but comprised those used on roads from New York to Tampa, Florida, North to South, and West as far as the Mississippi. Eleven of these were running to health resorts and places frequented by tuberculous patients. The examination of these were made at times when the travel to these places was at its height, and when to the writer's personal knowledge many cases of undoubted tuberculosis were occupying them.

Sixty-four animal inoculations were made from all these specimens with the result of positively identifying the tubercle bacillus only in one instance. It was thought to be present in one other, but this could not be confirmed by subinoculations in other animals. The pneumococcus was found in 5 instances, pyogenic streptococcus in 2, the staphylococcus in 2, colon bacillus in 2, hemorrhagic septicemia in 6, malignant edema in 1, streptothrix in 1, diphtheria bacillus in 1; the remaining 43 examined were negative and no pathogenic organisms were encountered.

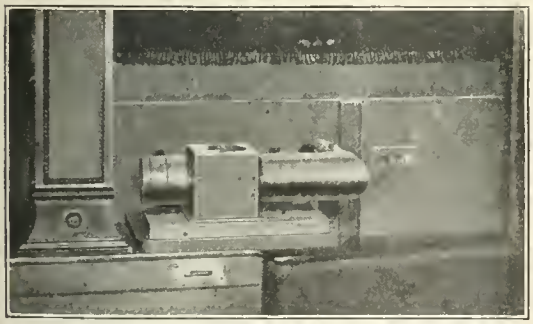
With regard to the one instance in which the tubercle bacilli was positively identified by subinoculations into other animals, this was a car which had run between Jersey City and Charleston, S. C. Its history was to the effect that many cases of tuberculosis had been carried to the southern health resorts on prior occasions, but none so far as could be ascertained were carried on this particular trip immediately after which the dust was collected. The other case, in which there is a doubt, came direct from Tampa, Fla., being returned empty to Jersey City as a "deadhead." No further history was obtainable. An inspection showed what appeared to be several spots of inspissated sputum on the cushion and on the carpet, about where the cuspidors are

usually placed. A microscopical examination made of these spots showed it to be sputum, but no tubercle bacilli could be identified. The animal inoculations made with the precipitate from this dust killed a guinea pig within 2½ months. On section there was found a small or circumscribed abscess in the axilla where the injection had been given, which to all appearances was tuberculous. Direct examinations made of the pus and histological examination showed bacilli, which in their morphology and tinctorial properties were identical with those of the tubercle bacillus. Careful examination made of all the organs for tubercles was negative. Subinoculations made with the tissue and pus from the abscess did not cause tuberculous lesions. Possibly this may have been tuberculosis, or on the other hand, it may have been one of the acid-fast bacilli, which possesses little or no pathogenesis. Yet their behavior to nitric acid and alcohol was identical with the controls made with cultures of the tubercle bacillus.

Bacteria in Air of Coach.—Pathogenic bacteria floating in the air is relatively of greater importance in disseminating disease than those fixed in the cushions, bedding, etc. It was first attempted to determine what relation the pathogenic varieties bore to the whole number present in a given amount of air, and then afterward what was the ratio between the number and that of passengers. The data obtained was not of such a character to be of any value in determining this on account of the many factors entering into the ventilation of the coach in transit.

Dust from the air was collected by means of a special apparatus (Figs. 1 and 2) by which the air could be aspirated from the coach when in motion.

Fig. 2.



Showing apparatus placed in position in car window for collecting dust.

The apparatus was placed whenever possible in one of the windows in the rear of the car, and varying amounts of air aspirated through it. The dust and bacteria were caught on sterilized glass wool contained in metal cylinders, the same as for collecting dust from carpets. Dust from 48 coaches was collected, and this was taken to the laboratory and examined.

The amount aspirated from each varied from 1,500 to 7,200 cubic feet. Twenty-seven of these were on runs to or from places in the South, where tuberculous cases go and one to Colorado Springs. The number of passengers was noted so far as was possible during the time of the collection of the samples. The number varied greatly. In some instances only two or three, while in others it was 24. The number, however, does not give an adequate idea of the total number occupying a coach during its trip. This is particularly so in coaches running between New York and the Southern cities, where it is not unusual to observe the greater part of coach population change two or three times before the end of the journey, only a small proportion being through passengers. It was also attempted to obtain information from the Pullman conductors, relative to the number of persons using such coaches during its whole trip, but on account of the unsatisfactory and fragmentary character of this data, it was not of sufficient value to be included. There were observed in the coaches under examination many cases of undoubted tuberculosis, and not a few of these were evidently suffering from the disease in its excavatory stage.

Fig. 3.

Showing aspirating device outside of car window.

Microscopical examination of the sediment obtained after centrifugalizing the watery suspension of the dust revealed particles of coal, sand, vegetable fiber, wool, cotton, epithelial and pus cells, yeasts, bacilli and cocci. A careful search made for the tubercle bacillus was negative in all instances. Plate cultivations made from several samples demonstrated the number of bacteria of each cubic foot of air ranged from 225 to 5,200; the number did not appear to bear any definite relation to the amount of dust, nor to the number of passengers. The colonies developing on these plate cultivations were those of yeasts, molds, streptothrix sarcinæ, micrococci

and bacilli. The pneumococcus, streptococcus, *Staphylococcus pyogenes aureus*, the colon bacillus and of hemorrhagic septicemia were isolated and studied.

The majority of the bacteria found in the air evidently had their origin, as would naturally be expected, from the outside air. Control experiments were made on several occasions contemporaneously with those made with car air, demonstrated the bacteria to be the same, with the exception that no pathogenic varieties were encountered, save the colon bacillus, which was isolated from the outside air in three instances; in two of these tests it was also isolated in the air of the car.

Ninety-six animal inoculations were made from these which gave the following results: Tuberculosis 1, pneumococcus infection 8, staphylococcus infection 4, general septicemia 5, malignant edema 1, negative 76.

The sample of dust which caused tuberculosis was collected from a Pullman car which ran between Tampa and Jersey City. It left New York on June 19, having an average of 10 passengers *en route*. The car was said to have been cleaned at Tampa. On its return trip it had 8 passengers from Tampa to Washington. The car was very dusty. 2,112 cubic feet of air was aspirated between Washington and Jersey City. A guinea-pig inoculated with a suspension of dust from this car was dead in four weeks after inoculation. Post-mortem examination showed pneumonia of both lungs due to *Streptococcus pyogenes*. There was also a caseous gland, somewhat enlarged, in the right axilla, at the point of inoculation, which contained bacilla resembling that of tubercle. The histological character was typical. This gland was emulsified and injected into other pigs. One of these died in four weeks after inoculation, and on section showed enlarged gland in the axilla which was caseous and contained tubercle bacilli. The retroperitoneal glands were enlarged and cheesy. Miliary tubercles were found in the spleen and liver.

The greatest number of pneumococcal infections from the air was obtained from the smoking cars. The air from the day coaches was negative in every instance. Observations of a similar character were also made on 39 other coaches which are not included in this report because of accidents either happening to the samples at or soon after their collection, or the time intervening between their collection and examination being so long as to vitiate their value, so these were omitted.

Bacteria of the Drinking Cup.—A bacteriological examination of 21 specimens obtained from the drinking cup of a Pullman coach demonstrated the pneumococcus 1, streptococcus 1, pyogenic staphylococcus aureus 1 and diphtheria bacillus 1. The pneumococcus was only slightly pathogenic, the streptococcus and and staphylococcus not at all, but the diphtheria bacillus caused the death of a 300 gram guinea-pig in less than four days. Subcultrues were recovered from the animal and made the subject of further study. While the number of pathogenic organisms isolated from the drinking cup is not large it is evident that it is one of the means of disseminating disease. It is suggested that some other arrangement should be made by which individual drinking cups at a small cost could be supplied in each car.

Method of Cleaning Passenger Coaches.—The methods vary considerably according to the time and place in Jersey City, where perhaps the largest number of cars are cleaned, the methods in vogue at the time of making these observations, were essential, as follows: (1) The carpets were removed by rolling them in bundles, and then taken to the cleaning shed. (2) The seats, cushions, pillows, mattresses and blankets were removed to a shed alongside the car, where they were beaten, dusted and aired; (3) men go through the car and dust all portions, including the upper berths, with feather dusters, immediately after which the upper berths are closed; (4) the charwomen wash the woodwork and glass with lukewarm water and castile soap.

The carpets after being taken to the cleaning shed, were placed on an elevation, which was covered with a heavy wire of about 6-inch mesh. These were then beaten with the ordinary carpet duster. Quite a number of the carpets, however, were cleaned by means of an air blast, the carpets being laid flat upon the floor and the apparatus conveying the blast of air passing over them. This seemed to take out the greater portion of dust, and was superior to the hand beating process. The rugs, particularly those of the smoking compartments, were, if badly soiled, washed with soap and water and then dried. After the carpets were thus treated they were replaced; the mattresses, pillows and bedding following.

The cars cleaned in Washington and Jersey City were treated in this way every other trip, being only swept at the end of each run. Those from Chicago, St. Louis, Jacksonville, Atlanta, Birmingham, Ala., and New Orleans, were cleaned every round trip.

The dusting of the bedding was done alongside the car. Many times this was done fairly well, but at many other times, particularly late in the afternoon or when the weather was damp or raining, they were not cleaned as well as they might be.

The same method was practised in Philadelphia, Washington, Chattanooga, Tenn., Asheville, N. C., and Jacksonville, Fla. (With regard to these latter it was usually done in the open air, the carpets being removed to a wire-covered rack and beaten; while the mattresses, bedding, curtains, etc., were taken out, shaken, sometimes beaten and usually exposed to the bright

sunlight for several hours. Strange as it may seem, the bacterial content of the bedding and carpets treated in this manner gave fewer bacteria than those in the car yards of Jersey City.

Compressed air was not in use at Jacksonville, nor at many places in the South. The objection urged against the use of compressed air at this place was that it seemed to cut out the pyle of the plush very much more rapidly than the process of hand beating, as there was so much sand always in these cars.

At St. Louis, Mo., the cleansing by the air blast had just been introduced. The car and its contents, with the exception of the carpets, was cleaned in rather a crude manner, too much confidence being placed in the air blast, and too little attention paid to the method of application. For example, attempts at dusting these cars were made by throwing a blast of air into the car with all windows and ventilators closed. This only resulted in setting free a cloud of dust, which afterward settled on the woodwork and cushions, which were not to be removed, except by a slight dusting.

The day coaches, particularly those of the Pennsylvania and Southern Railway companies, were cleaned far better than those of the Pullman Company, at least the examination of the dust after such cleaning showed a fewer number of bacteria than was always found in the Pullman coach.

The application of the air blast appears to be the best suited for this work. With due care in its application a greater amount of the dust from a car can be removed.

Health of Railway Employees.—In view of the fact that there seems to be a relation existing between the quantity of dust in the coach and septicemia produced by it in animals, and more particularly so with regard to the pneumococcus, a short notice regarding the health of the employees engaged in the cleansing and renovating these coaches would not be out of the way.

This was inquired into rather extensively at the car-cleaning sheds in Jersey City, where the major portion of the coaches east of the Mississippi are cleaned. Also inquiries of this character were made at Washington, Asheville, N. C., Chattanooga, Tenn., Jacksonville, Fla., Kansas City and St. Louis, Mo.

Many persons engaged in this employment are what might be called "transients," only taking service for a short time, or at irregular intervals. Little or no information could be obtained from those in charge of the work, about the health of these individuals, although none could recall an instance where any of these were "laid off" for any length of time on account of illness, and no history could be obtained with regard to them having been ill with cough or "lung fever."

There were, however, a respectable number of employees who had been constantly engaged in cleaning these coaches for a number of years. Three in the carpet-cleaning room, where nearly, if not all, of the carpets are cleaned by the hand-beating process, or by compressed air. Two had been engaged in this work for five and three years respectively, and another two years. All were present and at work at the time of inquiry and were to all appearances in good health. None had been sick, save with an occasional cold, which did not stop them from working for more than a week. No precautions of any character whatsoever were observed by those employees while engaged in work of this character. The room was constantly surcharged with dust and faces were blackened with it, but notwithstanding this they seemed to suffer no discomfort. Possibly these persons may have become immune(?).

No history of illness of any kind, suggestive of lung affection, could be obtained from the scrubbers, or those who engaged in beating and dusting cushions and bedding. The conductors and porters of these Pullman coaches were an exceedingly healthy lot. No one who was interviewed gave history of tuberculosis. Statements were made by these, however, that they knew of certain of their former number who had become ill from consumption, making it necessary for them to leave the service. Only three reports of this character, however, were obtained. Another instance of this kind came under the writer's observation, and that was a porter on a Western road.

As there seems to be a growing fear of tuberculosis among this class, and I have noticed, even at the time when these observations were made, and subsequently thereto, that a great deal of care was exercised by them in keeping the cars in good condition, particularly so if tuberculosis patients were passengers.

Ventilation of Coaches.—A number of anemometer readings were made for the purpose of determining the ventilation of these coaches. These were made in the top of the car, near the ventilators in the coach, on a level with the top of seats and also upon the floor. The data obtained was very unsatisfactory, and many times contradictory. Sometimes it would appear that the amount of air rushing out of the car was sufficient to change the whole content within a few minutes; at other times there appeared to be little or no ventilation, and particularly was this so on the level with the top of the seats. Here there was more or less movement of the air, due to the opening of the ventilators, windows and the doors.

After making quite a number of observations of this character, the writer became convinced that they would be of little value in determining this point, consequently they were abandoned. It then occurred to us to use some volatile substance, like ether, containing a volatile odor, and by spraying this at a given time in the for-

ward part of the car when the train was in motion, and then determine at what time the odor could be detected; this was done under many conditions. This test is admitted to be very crude, but it gave some idea of the ingress and exit of air. The shortest time in which the odor disappeared was seventeen minutes, all ventilators on one side open, also two windows partly open; the longest time was thirty-five minutes, three ventilators open. The interchange of air was many times greater in the upper third; here the odor was not appreciable after five or ten minutes.

Check observations were made by observing the time when a car became free from smoke, when suddenly filled, as for example after passing through a tunnel. This confirmed very closely to those made with volatile scents. Bisulphide of carbon also suggested itself as being an agent par excellence, but it was deemed advisable to employ it after an unexpected experience one night in Western Kansas. The writer was one of twenty occupants of a Pullman sleeping car. All the lower berths, and a few of the upper, were occupied. Four ventilators were slightly open. Just as the train was backing off from a siding, it came in contact, or in close proximity to a skunk. The air of the car was immediately surcharged with a most noisome odor. Everybody began to cough and ring for the porter, with frantic appeals to open doors, windows and ventilators. This was done as fast as circumstances would allow, but notwithstanding this it was at least thirty-five minutes afterward before order was obtained, but the odor did not disappear for an hour. On the following morning an examination showed that the truck on the rear car, the one just back of the one occupied, still smelled strongly of the odoriferous principle of the skunk, so it is safe to say that some of the outside air being surcharged with the odor was carried into the car and remained there at least an hour, if not longer.

Quite a number of improvements have been recently made in the ventilation of the railway coach, but it is yet far from being satisfactory. Particularly so with regard to the Pullman sleeping car. One of the most notable improvements in the ventilation of the passenger coach is the system now in use of the Pennsylvania Railroad Company, but it only applies to its day coaches. This system as devised is believed to be as nearly perfect as it can be made, without resorting to a mechanical forced draught. Unfortunately, this system as good as it appears to be for the day coach has not been considered practical for the ventilation of the Pullman car, in fact, it is doubted whether it could be applied, unless the interior of such coaches would undergo a complete rearrangement.

Perhaps a clearer idea may be conveyed in the following summary of the results of the animal experiments:

	Carpet dust.	Swabs.	Air.	Drinking Cup.
Negative,	8	43	76	17
Pneumococcus,	2	5	8	1
Staphylococcus pyogenes aureus,	3	2	4	1
Streptococcus pyogenes,		2	1	1
Bacillus tuberculosis,		1(?)	1	
Streptothrix,		1		
Colon infection,		2		
Diphtheria,		1		1
Septicemia,	1	6	5	5
Malignant edema,		1	1	
	14	64	96	21

Of the 196 animals inoculated with suspensions of dust obtained from the carpets, surfaces of the cars and from the air of cars it will be seen that 73 per cent., or 144 of these were negative. The largest number were those inoculated with dust from the air. Including those in which the tubercle bacillus was positively identified there remains 21 per cent. of the animals which died of affections other than tuberculosis. Possibly there were some animals included in this number, which may have died of tuberculosis, or of diphtheria, but were killed by a rapid infection. If this is so, the percentage for tuberculosis and diphtheria may be increased. In view of the fact that a considerable number of the animals died very early after inoculation many more such experiments must, therefore, be made before we can arrive at a final conclusion.

The above observations and experiments are submitted for whatever value they may be in adding to our knowledge of the sanitary status of the railway coach. There is no desire on the part of the writer to draw any hard and fast conclusion from the above experiments, for he believes that the data herein submitted is not sufficient to warrant this. Therefore, many other questions regarding the sanitary condition of the railway coach must be solved before its actual condition is known. The only fact which seems to have been proven in this investigation that as much as 73 per cent. of the animals inoculated were negative, thus demonstrating that the bacterial content of the railway coach in the majority of instances examined was not infectious to animals.

The writer wished to continue this investigation in order to cover these lapses, and representations were made at the time when these observations were suddenly brought to a standstill, that the inquiry should be continued much further before sufficient data was collected to settle these points, but he was informed that the investigations had advanced sufficiently to show the conditions of the railway coach, and it was not deemed advisable or expedient for him to pursue the subject further. Notwithstanding this adverse action it was the intention of the writer to continue this at some future time, but so far this opportunity has not presented itself.

It is to be sincerely hoped that these few experiments and observations, few and fragmentary in their nature, will serve as a stimulus for further investigations in this important subject, and that proper authorities, either state or national, preferably the latter, will take up this work on this or other lines and furnish the much-needed information. Probably this may be done, as I am credibly informed that the Public Health and Marine Hospital Service now considers some further investigations are necessary to be made regarding the sanitary condition of the railway coach. The writer hopes that this is true.

In closing acknowledgments are made to the various railway officials for the many courtesies and cooperations the writer has received from them, to the Pennsylvania Railroad Company, the Southern Railway and the Pullman Car Company, to whom special acknowledgments are due, and also to my colleague, Dr. Ezra K. Sprague, late Assistant Director of the Hygienic Laboratory, who assisted me in this work.

THE CURE OF LEPROSY.[1]

BY ISADORE DYER, PH.B., M.D.,
OF NEW ORLEANS, LA.;
ASSOCIATE PROFESSOR ON DISEASES OF THE SKIN, MEDICAL DEPARTMENT, TULANE UNIVERSITY; PROFESSOR ON DISEASES OF THE SKIN, NEW ORLEANS POLYCLINIC; VISITING DERMATOLOGIST TO CHARITY HOSPITAL; CONSULTING DERMATOLOGIST TO THE EYE, EAR, NOSE AND THROAT HOSPITAL, NEW ORLEANS; CONSULTING LEPROLOGIST TO THE LOUISIANA LEPER HOME.

"And the leper in whom the plague is, his clothes shall be rent, and his head bare, and he shall put a covering upon his upper lip and shall cry "Unclean, unclean." All his days wherein the plague shall be in him, he shall be defiled; he is unclean. He shall dwell alone; without the camp shall his habitation be." (Leviticus, xiii: 44.)

WHEREVER, in historic reference, levitical guidance, holy appeal, or in divine interference, remark of leprosy has been made, the leper has been indicated as a morbid element in the field, and in Mosaic, Talmudic of Mohammedan law the victim of the disease was always classed among the living dead.

Small wonder that the humanitarian evolution in centuries of material progress should have cast aside even the slightest attempt at remedying more than the evil of the existence of the disease; and that this should have been only arrived at through the crudest and most barbaric methods.

Here and there in the modern world some desultory charge was taken of leprosy, at times directed at the care of the afflicted, but more for the protection of the public. Wherever, however, a leper came into existence, there was hardly more than a casual interest excited, or a bit of passing pity for the immolated.

So long as the epochal story of leprosy is told, and so long as the world finds time to listen to the dramatic theme, the name of the Belgian martyr priest, J. Damien de Vuester, must ring out in no uncertain tones. He was called by an inspiration to a solemn duty, which he fulfilled so well that with the word "leprosy" to-day the name of Father Damien sounds an echo. Unconsciously he worked out the signal which the time demanded: First, the world needed to be aroused to the conditions, and second, that only by his trying the hope of the leper might be awakened to a thought of better things amid the chaotic inaninity of their state of neglect and abhorrence at the hands of the rest of mankind.

With Father Damien's death in 1889, the thought of leprosy was spread throughout the world. The public prints heralded the exit of the priest and noted what had been done by him. The genesis of modern views of the disease so far as its care and treatment are concerned date from this time.

The British government in 1890 and 1891 located a qualified commission in India to investigate the disease. The death of Damien, as a statement in the introduction to the report of this commission affirms, was responsible for this step. "His martyrdom did not appeal in vain to humanity." The report of this commission was widely disseminated and excited a similar study of leprosy wherever the disease was found. Desultory reports followed, until the interest of the whole world centered and was crystallized in the Berlin Leprosy Conference in 1897.

A large opportunity of research was opened up. Even those living in leper centers differed as to the method of spread of the disease. When the real purposes of the aggregation of nearly two hundred men appeared, the mighty step forward began to show itself. That gathering lifted the whole atmosphere of leprosy out of the beclouded bigotry of uncharitable medievalism into the broad light of a humanitarian civilization. More than that, it demonstrated the need of considering leprosy as a combatible evil, and it approached, with stern argument and pure wisdom and reason, the avenues leading not only to the control of the disease, its future prevention, but even the probable cure of the fell malady.

Among the facts deduced were the actual numerical occurrence of the disease; the hardihood of many observers in their patient pathological investigations, resulting in the demonstration of the germs in every organ of the body, the measures already in vogue in many countries, the absolute denial of heredity in the etiology of the disease, and a better argument for contagion as the cause.

More than this; sufficient argument was brought to bear to make it almost certain that the channel of entrance of the contagion was through the mouth and nose. Since 1897, the work has gone on. Enlightened care of the disease is now practised the world over.

The ignorance of the profession with regard to the disease, the general indifference of the public and the fear of the leper himself have all

[1] Read before the Texas State Medical Association, Houston, April 27, 1905.

helped to prevent a better care or a better knowledge of this disease.

Popular conceptions of leprosy have been entirely derived from scriptural interpretations. Graphic as it is, the impressionist picture which Lew Wallace presents in "Ben Hur" is far from the actual state of the leper. Mosaic law defined the disease and classified types which to-day we know to be different diseases, some of them not leprosy at all. The "white scaling leprosy," the "leprosy of open sores," were the one a mild innocuous skin disease, the other only the common "seven years' itch." True leprosy is described in the Bible, however, and sufficiently so to have led to its more exact study.

To-day the exact types of the disease are known and recognized. In older countries, as in the Orient, Norway and Sweden and in China and India, where the disease has existed indefinitely, the phases of leprosy vary from insignificant markings of the disease to horrible mutilations, so transforming the person afflicted as to remove all semblance to a human form. We recognize, however, leprosy as a distinct disease, capable of exact study and determinable at the slightest evidence.

There are two general forms, that of nerve type and that of skin leprosy, both starting alike but varying as the symptoms develop. The picture of nerve leprosy is that which is the more appalling; that of skin leprosy the more horrible.

Nerve leprosy begins with small warning, flashes of eruption here and there, spots of reddish brown which come and go, small blisters on the hands and feet which either superficially form and dry leaving slight marks behind, or which leave ulcers, growing deeper and deeper until a part of a finger or a toe dries up or falls off leaving the stub behind. Sometimes there is only a loss of power in the member. The victim of the disease drops things, feels numbness of the fingers, burns himself without knowing it. Then there is contraction until the hand becomes a claw, the muscles atrophy and the flesh shrinks away, leaving only the skin and bone. Not only fingers but even the muscles of the face may do the same; the hair falls and staring eyes look out of a hairless face; the skin grows wrinkled, dry and then over bones a thinned and parchment skin covers what was once a rotund visage. The ears lose tone and hang like bits of pendulous leather on the sides of the head; meantime the gums recede, the muscles of the throat become affected, the voice first changes to a metallic note and then drops to a raucous whisper. Ulcers come on the hands and feet, and then God is merciful, the leper loses the balance of his brain control and drivels as an idiot or passes into a paretic state, softening of the brain, and he dies forgetful of the way in which the grim destroyer has snatched the brand from him, with eyes blinded and his senses stunned or bereft of the reasoning power.

Skin leprosy is more patent. Thickening in reddish patches usually, on the face and hands, as well as other parts; the skin grows tense, masking the face and giving to a skin of normal shape a fixed and tanned hue. Here, too, the hair falls, and the expression is that of a satyr, lips thickened, eyelids dense, and eyes glassy and staring in the leprous change. Here and there the masses of flesh rise above the skin forming nodose areas, some small, some large. At times these lumps, really tubercles, come fresh, in twos and threes, massing around the nose, on the ears, on the lips, and on the hands; they grow to the size of acorns, deep red and brown in color. Then they run together forming alternate nodose bands and deep depressions, almost like a perpetual smile, were it not for the fact that the everted lips and glistening teeth make the grin that of a fury. Once these bumps or tubercles reach their maximum in size, scabs start, the color becomes a deeper brown and the expression grows truly leonine, except that the eyes are furtive—staring as if in perpetual night. The voice sounds a note of nasal tone—at the same time raucous as if a high nasal note were interrupted by the filing of a saw.

How far we have come from those days when the leper found his only treatment in a sought-for surcease in the cities of the living dead: from that time when on his lip he bore the leathern thong which named him, even before he cried, "unclean, unclean." Carry the picture of the leper scourged with thorny brush until his bleeding sides begged pity or else the means to end his unwelcome life. Farther along let's draw the picture of the native of the Fijis wrapped in shrub and herb and laid upon a pyre, his blistering limbs yielding either to the loss of flesh or else giving way to death in the hope of survival. Among the South Americans even to-day the lepra victim submits his life to the bite of venomous reptiles in the hope that by this means he may recover, and, if not, that he may succumb in the process, rather than spend his life in exile.

To-day in India, Hawaii, Japan, the British Colonies, in Russia and in almost every civilized country in the world, fairly decent habitations have been provided, and in some even proper domestic and medical care. More than this, the treatment of the disease has been lifted from barbaric custom into scientific practice, and in almost every therapeutic field, serum, medicinal and hygienic, treatment has been essayed to ameliorate, and even in the hope of cure. No longer is the leper set aside to end his days in watching members, one by one, to fall away; he realizes that intelligent direction has mapped the road which leads no matter by how many turns to a possible relief. Empiricism and exact laboratory experimentations have added much to the knowledge of the treatment of this disease, and to-day we have arrived at the conclusion that here, as in any other field of nature, the combat is between the morbid and the true.

I believe leprosy is curable. I believe leprosy is curable as I believe syphilis is curable and as I believe tuberculosis is curable. There are cases of all three diseases which are only arrested and others which do not respond to any treatment and which destroy the patient in their processes.

Twenty-five years ago the victim of tuberculosis was condemned to die of the disease and the way was made easy for him. Syphilis, even to-day, is looked upon as incurable by the conservative, and yet both of these diseases, like leprosy, are self-limited diseases. According to the degree of original infection, according to the condition of body resistance and stability of the victim of the disease, any of these three diseases will run a limited course, get well of themselves, or, under conditions of life favoring a higher degree of resistance, the disease is arrested after a time. With added care and treatment, with measures directed at increasing the resistance, this may be raised to a point where the disease can no longer hold its place in the economy and the patient recovers from the disease sufficiently to be free of all evidences during the rest of his life.

Applied to syphilis, applied to tuberculosis, applied to any disease of infective type, the patient is called well of a disease when that disease presents no evidences of its direct or indirect effects after a reasonable time. With syphilis the control of all symptoms, and the failure of appearance of others, after a careful treatment, allows the acknowledgment of a cure sufficiently for the person with such an experience to engage in matrimony and to beget or bear healthy children. The freedom of all physical signs of the disease, with the evidence of a perfect general health, resulting after careful treatment and training of a tuberculous subject, demands the acknowledgment that such an individual is well of the disease.

Now, in what particular way should leprosy differ from these two? Even where leprosy stalks a fearful enemy of civilization—a curse and a blight upon the nations it destroys—the hand of horror has been raised against it to such an extent that even men of the medical profession have silently let these unfortunates go the way of their antecedents because they were unwilling to inquire into the disease or to essay methods aimed at the relief of such an affliction.

Here and there earnest workers have marked some way leading to a remedy, and wherever anything has been done, it has simply become a part of the foundation on which the present stand has been taken.

The ravages of smallpox were stopped by Jenner's discovery, and then it was ascertained that under some degree of protection this disease could be cured. The plague stands to-day as a barrier in places where the investigations of its methods have resulted in preventive measures, and I tell you that when an intelligent effort is made to treat leprosy it will fall in its natural place among remediable ills, and it can be treated just exactly as the other loathsome diseases have one by one yielded to scientific procedures.

Every disease represents the acceptance by the human economy of a foreign substance, more or less parasite upon its energy, the degree of which is directly dependent upon the ability of an individual to resist. Communities survive their evils, and races die or go on to fulfil the supreme fitness of their intention directly as they may develop the inherent and instinctive quality of resistance. Disease is a direct parallel, and each type, whether in chronic or acute forms, bears a likeness to the theory.

Leprosy begins with the acceptance in the economy of the bacillus, and if it finds a fit soil in which resistance is below the normal, it spreads, in degree, to one or to every organ in the body. Its colonists are like the people of a sturdy race, finding new fields of entry, and whenever a good location is determined, there they settle, and then next consume in their development the tissues in their vicinity until the germ survives and the tissue dies.

Remedial measures are directed at flooding the field of infection, massing an amount of tissue on which the bacillus cannot feed, but which acts as fuel for the development of normal tissue; this, aided by the natural process of nature, gradually lays siege to the undeveloped foreign tissue until this is carried off or disseminated through the organs of elimination of the human body.

That the fight is a long one must be evident because no siege was ever accomplished without well-laid plans. The tone of the patient with leprosy must be raised gradually to a point where specifics in the disease may be given, where experimentation may be allowed. Many an essay of possible success has been discounted by the failure to appreciate the necessity of beginning this in an individual prepared for the trial.

As yet there is no treatment which can be said to cure all cases of the disease, but a multitude of workers are traveling along the lines leading to the avenue of final success. Each man who works in the field where leprosy exists, has, now and then, seen a ray of light pointing to a final solution. There is no evil for which nature has provided no remedy, and it remains for some discoverer to find the one for this. Meantime a life is, here and there, snatched from the leper's fate, and whenever another is added to those already cured it means just one more signal of hope to the darkened spirit of those who live in that state which, formerly, was indeed a synonym for despair.

The treatment of leprosy must be based upon the individual case. In Louisiana we have striven with various remedies but the results have been based on the physiological state of the patient.

I saw my first case of leprosy in New Orleans

in 1893 at the Charity Hospital. In June of 1894 I had seen twenty-five cases; up to April, 1905, I have seen 224 cases in Louisiana, six cases from Texas, one from Mississippi and one from Alabama: I have also seen two cases referred to me from distant States. My early experiences with leprosy were far from reassuring. The Leper Home had become an asylum, without hospital management or pretension, and persons not in the Home would avoid clinics and public places for fear of being sent to the Home.

My first attempts at the treatment of leprosy were based upon the experience of others. In 1894, the accepted treatment of leprosy was with chaulmoogra oil, hoang-nan, strychnine, arsenic, gurgun-oil, salol, salicylate of soda, ichthyol, europhen, and bichloride of mercury. No success with any of these had been reported, although chaulmoogra oil evidently occupied the position of being a remedy capable of ameliorating the disease.

Beginning in 1894, I have employed a number of remedies in treating leprosy with varying results, which it is the object of this paper to relate. It must be remembered that each case treated was treated under the most adverse circumstances. Some patients were not seen for months apart; while others would take treatment quite irregularly.

I have already stated that I believe leprosy curable. In ten cases to be related below I have demonstrated this. I wish further to state that no case of leprosy, in early or not advanced types, has failed to respond to treatment; amelioration occurs invariably and where treatment has commenced early enough and has been kept up long enough a certain number have recovered.

I have used at various times the following remedies: ichthyol, solicylate of soda, arsenic, strychnine, bichloride of mercury, chaulmoogra oil, antivenomous serum, normal horse serum, red mangrove bark, the derivative fatty acids of chaulmoogra oil.

The only remedies giving results were: strychnine, antivenomous serum, chaulmoogra oil, chlorate of potash.

With chlorate of potash one case was rid of all lesions in three weeks' time, but he did not maintain treatment and relapsed.

In 1897, I began experimenting with Calmette's antivenomous serum. The occasion which led me to this treatment has already been related in my paper presented to the Berlin Conference (*New Orleans Medical and Surgical Journal*, Oct., 1897). In that paper the results obtained were interesting. Of the cases there reported, five in all, one died unimproved, another subsequently materially improved under chaulmoogra oil, a third disappeared, while two cases entirely recovered. Of these two, one was a policeman, who, since 1897, now eight years, still fulfills his usual task, and *has had no treatment since* (excepting strychnine). The other, a carpenter, resumed his work, had no return of the disease, *without further treatment* (excepting strychnine). He died, however, of pneumonia, during the winter of 1902.

The serum was not at all effective in a series of cases afterward experimented with, but I attribute this result largely to the facts that the serum was not always fresh and that the expense attached prevented as full dosage as would have been indicated. Woodson's report of the use of the serum in one case shows that others did obtain results.

At the suggestion of Calmette himself, I experimented with normal horse serum—prepared expressly for me by Messrs. Parke, Davis & Co. This treatment was essayed in a series of eight cases for over a year but without results. Ichthyol, salicylate of soda, etc., likewise failed to secure results.

Chaulmoogra oil had been used so long for leprosy and with apparently such good results, *up to a certain point*, that it occurred to me to experiment with the derivations of *crude* chaulmoogra oil. Accordingly, Messrs. Parke, Davis & Co. separated the oil into its fat acids and delivered these to me with the residuum of the waste. I made pills of each of the acids and of the waste and experimented with each of these separately and combined. Again without result. In the meantime I was employing the usual stock chaulmoogra oil in most of my cases, but without permanent results.

I then asked Messrs. Parke, Davis & Co. to supply me with chaulmoogra oil in as crude a state as they could and yet have it in liquid.[1] I secured a quart of such oil and began now giving this in maximum doses. The results have been better than ever before and I believe that such oil more nearly approximates a specific for leprosy than any treatment as yet suggested.

Detroit, Mich., U. S. A., June 8, 1904.

1 Isadore Dyer, M.D.,
124 Baronne Street,
P. O. Box 278, New Orleans.

Dear Sir: Under date of May 12, we wrote you that we would postpone a final report on chaulmoogra oil, pending an attempt to obtain more definite information as to the source and process of manufacture from our Importing Branch in New York.

We are sorry to have to say that no one in this country to whom we have applied has been able to get us any definite details as to the manufacturing process. We are to-day addressing a letter to our Indian representative, and hope to obtain through him some further facts of first hand; as it will be some weeks before we can obtain a reply from this gentleman, we hand you herewith such excerpts from the literature as we think may be of some interest to you. As you will see, this information pertains rather to sources of supply than to the method of manufacture.

In Flückinger and Hanbury's Pharmacographia, the following statements are made:

"*Botanicol Origin.*—*Gynocardia odorata*, R. Br. (*Chaulmoogra* Roxb., *Hydnocarpus*, Lindl.), a large tree with a globular fruit of the size of a shaddock, containing numerous seeds immersed in pulp. It grows in the forests of the Malayan peninsula and Eastern India as far north as Assam, extending thence along the base of the Himalaya westward to Sikkam.

"*History.*—The inhabitants of the southeastern countries of Asia have long been acquainted with the seeds of certain trees of the tribe (*Pangieae* (ord. *Bixineae*) as a remedy for maladies of the skin. In China a seed called Ta-fung-tsze is imported from Siam, where it is known as Lukrabo and used in a variety of cutaneous complaints. The tree affording it, which is figured in the Pun-tasao (circa A. D. 1596) has not been recognized by botanists, but from the structure of the seed it is obviously closely related to *Gynocordia*.

"The properties of *G. onorata* were known to Roxburgh, who, Latinizing the Indian name of the tree, called it (1814) *Chaulmoogra odorata*. Of late years the seeds have attracted the notice of Europeans in India, and having been found useful

During the several years of my observation of leprosy I have acquired certain points which I have noted in the treatment of these patients.

1. Full diet, restricting only indigestible foods is indicated. The disease seems in nowise to be affected by fish or any other particular article of diet.

2. Baths are essential in the treatment. Hot baths twice a day, with or without soda, are effective.

3. The patient needs tonics, febrifuges, and should be watched for intercurrent or complicating diseases, such as malarial infection, pleurisy, pneumonia, grippe and the like.

4. Strychnine is a *sine qua non* in the treatment of leprosy. My assistants and I lay down the rule that a leper should always take strychnine—the sort and size of dose to be regulated by the patient himself.

5. When chaulmoogra oil is given it is better endured before meals than after. It is best taken in capsules, in hot milk, or in milk of magnesia. The dosage should be begun small, say 3 drops, and increased every second or third day until as much as 120 to 150 drops of the oil are taken at the dose.

At times it is advisable to give the oil in pill form. This can be done either combining it with extract nux vomica and ordinary excipients or a very effective way is with tragacanth and common soap.

6. Above all things individualize the patient. Watch for improvement and if it does not show in three months wait six months—if it does not show in six months, wait a year, or longer. But keep on driving at the treatment until the patient dies or gets well. I have on record one patient who did not show any signs of improvement for two years, but who is now well.

7. When all evidences of the disease are gone, insist on a continuance of treatment. It may not be necessary, but it makes sure.

I am not the first to argue the curability of leprosy. Every center of leprosy shows the disease one which runs a natural course. Sometimes fulminate and destroy the patient in a few months. Other cases are slow in their onset and are slow in their outcome. Yet other cases will show small evidence, which disappears, leaving no trace and never returning. There are all grades of the disease, and the care of each must be as each directs. It only remains for me to tabulate those cases of my own which in my opinion are cured of the disease.

Case I.—Lizzie O'C., aged nineteen years; first came under observation at the Charity Hospital in the early part of 1894. She presented characteristic macules on both legs. On her left foot, plantar surface, under the ball of the great toe there was a typical trophic ulcer, with the odor and process characteristic of this leprous manifestation. Treatment with strychnine and chaulmoogra oil was established. In six months the lesions of the disease disappeared and after more than a year had not returned.

Case II.—Martin O'C., father of Case I. Disease developed seven years after it had appeared in daughter. This case presented the following history: Aged sixty-two years; native of Ireland. Laborer. Seen at Charity Hospital in the fall of 1895. Lesions presented: One large leprous macule on the forehead; one on the arm of the right side and one on the leg. All of these were uniform in size, being about two inches in their long and one and a half inch in the shorter diameter. The lesions were in the form of irregular ellipses of a dull red color and somewhat elevated. Anesthesia was marked in each. The eruption had been out only a few months and because of the rapid recovery of the daughter she had brought her father for treatment. The evidences of the disease rapidly disappeared under strychnine and chaulmoogra oil. The patient reported for observation for six months.

Case III.—August R., male, aged forty-seven years; native of Louisiana. Macular anesthetic leprosy, trophoneurotic type. Came under observation in April, 1897. The antecedent history in this case was clear. Periodic attacks of rheumatoid pains in the right arm and forearm were followed by first a sense of numbness and then contraction of the fingers. When seen the arm

---

in certain skin diseases, they have been admitted a place in the Pharmacopoeia of India.

"*Chemicol Composition.*—The kernels afforded us by means of ether 51.5 per cent. of fatty oil, which is almost colorless, or somewhat brownish if the seeds are not fresh. Either extracted or expressed it is of no peculiar taste. The pressed oil concretes at 17° C.; that extracted by ether or bisulphide of carbon requires for solidification a lower temperature. The expressed oil is slightly fluorescent, less so than that extracted by means of bisulphide of carbon. If the oil, whether pressed or extracted, is diluted with the bisulphide, and then concentrated sulphuric or nitric acid is added, no peculiar coloration is produced.

"*Uses.*—The seeds are said to have been advantageously used as an alternative tonic in scrofula, skin diseases and rheumatism. They should be freed from the testa, powdered and given in the dose of 6 grains gradually increased. Reduced to a paste and mixed with simple ointment, they constitute the Unguentum Gynocardiæ of the Indian Pharmacopoeia, which, as well as an expressed oil of the seeds, may be employed externally in herpes, tinea, etc.

"*Substitute.*—It has been suggested that the seeds of *Hydnocarpus Wightiana Bl.*, a tree of Western India, and of *H. venenata Gartn.*, native of Ceylon, might be tried where those of *Gynocardia* are not procurable. The seeds of both species of *Hydnocarpus* (formerly confounded together as *H. inebrians* Vahl) affords a fatty oil, which the natives use in cutaneous diseases."

In "Animal and Vegetable Fats and Oils," by Brannt:

"Chaulmoogra oil from *Hydnocarpus odoratus*, Lindl., a large tree found in the forests of the Himalaya, in the East Indies and Malayan Islands. The seed yields by expression over 30 per cent. of oil, and when extracted by ether 50 to 52 per cent. Chaulmoogra oil, when not entirely fresh or pressed from old seed, has a characteristic (bird-glue like) odor and taste, and is somewhat brownish; otherwise it is hard and without taste or odor. The expressed fat is hard up to 62.5° F., the extracted only to 57° F. In India, China and Siam the oil is used for many purposes, but specially as a remedy for rheumatic gout, and various diseases of the skin."

Squire's "Companion to the British Pharmacopoeia," edition of 1890:

"Chaulmoogra oil is obtained from the seeds of *Gynocardia odorata*. The oil has been long known and used in India; it is solid, of a light brown color, with a disagreeable taste and smell, and can be readily melted by a gentle heat. It has been recommended in the treatment of leprosy, psoriasis, obstinate eczema, and other skin diseases, chronic rheumatism and gout, and secondary syphilis. Good results have been obtained from its external as well as internal administration in phthisis. Chaulmoogra oil contains about 12 per cent. of an active principle, Gynocardic acid."

In the *Pharmaceutical Journal of Great Britain*, of May 12, 1900:

"*Notes on Chaulmoogra.*—It appears that the seeds of chaulmoogra met with in commerce, and generally considered to be the product of *G. odorata*, differ materially from those of that species. D. Hanbury ("*Science Papers*," 244) describes and

was swollen and the ulnar nerve somewhat thickened, with a nodosity the size of a hazelnut just below the elbow.

The last three fingers were contracted and could not be straightened, the effort to do so causing pain along the whole forearm. On these three fingers there was an eruption of bullae, in size about that of a silver dime; in number four or five. On the dorsum of the hand there were typical anesthetic macules. The anesthesia could be well determined fully one-third the way up the ulnar side of the forearm. From April 6 to June 22 salicylate of soda, strychnine, iodides, were given with varying result so far as the pain was concerned. The deformity persisted. On June 28, injections of antivenomous serum was begun. In all 11 injections were given in doses varying from 1½ c.c. to 3 c.c. and injected in various points of the body, chiefly along the ulnar nerve and in the interscapular area. Total amount injected 34½ c.c. On August 30, 1897, the following note was made: "There is faint rosiness over base of third finger, at second and third joints and over last phalanx; the same discoloration over the phalanx of little finger. The patient has complete use of the hand and forearm and complains only of stiffness at night in the third finger. He has improved in general health and weighs 186 against 174 pounds at beginning of injections."

This patient took strychnine sulphate in 1-60-grain doses throughout, and this was maintained afterward for some months. In January of 1898, there was no evidence of the disease and up to 1902, when patient was last seen, there has been no further evidence.

Case IV.—Henry P., male, forty-five years old; carpenter. Macular anesthetic leprosy, with trophic changes in the left hand. First seen November, 1896, at the New Orleans Polyclinic. The evidences of leprosy presented were as follows: Face, general duskiness, without distinct lesions. Ears thickened. Back, one small macule over the loin. On the right arm a distinct mottled lesion, just at the origin of the ulnar nerve; it was irregular in shape, rather ovid, with the long axis running diagonally across the inner aspect of that part of the forearm. Lesions dark brown, reddish. On the left arm, one lesion just at elbow-joint. On the outer aspect of the arm, another lesion like that on the right arm. On the flexor surface and inner aspect of this forearm, three inches above the wrist, a lesion as large as a silver dollar, purplish brown in hue. On the third finger, dorsum, deep purplish lesion, running the entire length of the finger. A similar lesion covered the first phalanx of the second finger. The left hand presented the characteristic claw hand. On the right thigh a large round lesion, 1½ inches in diameter. All lesions markedly anesthetic to pain. Up to July 7, 1897, patient had been treated variously with chlorate of potash, salicylate of soda, together with strychnine, without result. The strychnine was continued and antivenomous serum injections begun on July 7, 1897. A total of 18 injections were employed, 48½ c.c. in all; maximum injections 5 c.c.; minimum, 1 c.c. A note made August 30, 1897, relates that the lesions had disappeared in half their total area. The full use of hand restored. All injections had become painful and the patient had gained five pounds in weight. The injections in this case were kept up at less frequent intervals until the spring of 1898, when they were discontinued because of the difficulty of getting proper serum. The strychnine was maintained, however, and the patient reported regularly for observation. In June, 1898, he resumed his work as a carpenter, with no evidence of the disease left about him and without any recurrence whatever up to 1902. Then he died of pneumonia.

Case V.—K. G., aged forty-five years; merchant. Presented July 20, 1898, with some six leprous tubercles on his face and as many more distributed on different parts of the trunk and

figures Chinese chaulmoogra seeds as imported from Siam into China, as having foliacious, lanceolate cotyledons, which he recognizes as not being identical with *Chaulmoogra odorata* of *Roxburgh*, that authority describing the cotyledons of C. odorata as being subreniform, with the radicle variable. Notwithstanding this, in works on materia medica and in museums, the chaulmoogra seeds of Hanbury are attributed to *C. odorata*. G. Desorez has recently received from Calcutta specimens of both seeds. He describes the true *Chaulmoogra odorata* seeds as being larger, less uniformly gray, the testa being marked with dark patches. The integuments are not so brittle as in the ordinary kind, the kernel is reddish and marked with white. The cotyledons are thick, subreniform, the radicle placed at the side. These seeds contain a large amount of hydrocyanic acid. The seeds generally met with in commerce ar uniformly gray in color, the integuments are brittle, the kernel is dark in color, with a rough surface, the cotyledons are foliaceous-lanceolate, and the radicle direct, as described by Hanbury. These seeds contain no prussic acid." *Journ. de Pharm.* (6), 11, 316.

In the *Pharmaceutical Journal of Great Britain*, May 11, 1901, there occurs the following note by E. M. Holmes, Curator to the British Museum:

"Allusion has generally been made in this journal to the fact that chaulmoogra seed has been supposed to be yielded by another plant than *Gynocardia odorata*, but hitherto, in the absence of specimens, and judging from the meager information afforded in the *Journal de Pharmacie*, it has been impossible to publish full information concerning the facts. In the *Indian and Colonial Addendum to the Pharmacopoeia*, under Oleum Gynocardiæ, the oil is stated to be the fatty oil expressed from the seeds of *Gynocardia odorata*, or of *Gynocardia proinii*, Desprez. As a matter of fact, neither the chaulmoogra seeds nor the oil are obtained from *Gynocardia odorata*, but from an undescribed tree which M. Desprez proposed to call *Gynocardia Prainii*, in honor of Dr. D. Prain, the Director of the Calcutta Botanic Gardens. Dr. Prain, however, in a letter to me, accompanying the excellent specimens of the seeds sent by him for the Museum, states that so far as the imperfect material in his possession permits he has formed the opinion that the tree which produces the chaulmoogra seeds of commerce does not belong to the genus *Gynocardia* at all, but probably to the genus *Hydnocarpus*. He will not be able to determine this point satisfactorily until the tree flowers (which may not be until June), when he will communicate a note on the subject of our journal. The seeds of *Gynocardia odorata* are quite different to chaulmoogra seeds, having the radicle laterally placed, giving off hydrocyanic acid when moistened, and having a thinner testa."

In *Pharmaceutical Journal of Great Britain*, Sept. 14, 1901:

"*Oleum Gynocardiæ* is obtained by expression from the seeds of Taraktogenous kurzii, King (N. O. Bixaceæ), a native of Burmah. The oil possess alterative and emetic properties. It is administered in the form of an emulsion, or mixed with other oils, and the dose is from 5 to 10 minims, gradually increased to 0.5 to 1 fluid dram.

"*Characters and Test.*—Chaulmoogra oil is a brownish-yellow oil, or fat, of varying consistence, having a characteristic odor and a somewhat acrid taste. It has an acid reaction, and may fully liquefy only at 42° C., resolidifying in different periods, at temperatures from 15.5° C. upward. The specific gravity of the oil is also not constant, but is usually from 0.030 to 0.954 at 30° to 40° C. The oil is soluble in purified ether, chloroform, or carbon bisulphide, and the greater part of it is dissolved by cold 90 per cent. alcohol, the remainder being dissolved by repeated treatment with warm alcohol. A little insoluble, non-fatty matter is sometimes present in the oil, and causes turbidity of solutions in the liquids mentioned. A reddish-brown coloration, changing to olive-green, is produced on mixing twenty drops of the oil with one drop of strong sulphuric acid.

legs. Each of these was fully as large as a small marble and characteristic in clinical appearance. One of the tubercles was excised and the leper bacillus demonstrated. Patient was put under treatment but inside of three weeks his face was covered with new lesions; proportionately as many developed on the rest of the body. As this case had developed altogether in less than three months he was advised to change climate and left New Orleans. He returned at the end of two years, having been subjected to very rigorous treatment in Europe, and on my examination was found free of the disease. Since 1900 I have seen this patient at regular intervals of four or six months, and there has been no evidence in any way whatsoever of a recurrence. His treatment consisted in strychnine and chaulmoogra oil.

Case VI.—Mrs. G. Peterson, aged twenty-seven years. Applied for treatment at the Charity Hospital, September 22, 1899. She presented a deep-seated macular leprosy tubercle the size of a silver dollar on the right side of her neck. There were two lesions twice this size on each leg. On both hands there were leprous nodules and the ulnar nerve on the left side was perceptibly enlarged. Some contraction of the two last fingers. Patient took strychnine in 1-50-grain doses and chaulmoogra oil in increasing doses until 40 drops at the dose were taken. In October, 1902, there was no evidence of the disease. This patient has reported regularly at intervals of every four months up to the present time, and there has been no recurrence.

Case VII.—Blanche B., aged twelve years. Reported for treatment July 22, 1901, presenting a typical lesion the size of a silver quarter over the right maxillary region. Another lesion as large as the palm on the right leg. Both typical leprous macules. One-sixtieth-grain doses of strychnine sulphate and increasing doses of chaulmoogra oil were administered. A maximum of 30 drops was reached. In June, 1902, both lesions had disappeared. Treatment was continued until 1903. Patient has reported at intervals since then and there has been no recurrence.

Case VIII.—A. G., aged thirty-three years; female. History of the disease of ten years' standing, progressively increasing until I saw the case. At this time the face was covered with ulcerating tubercles; the hands were considerably swollen, here and there presenting bullae and ulcers of typical character. No area of the body was free of discoloration, macules or tubercles. Treatment was begun in March, 1901. One-fiftieth grain strychnine sulphate was administered three times a day. Chaulmoogra oil was given in increasing doses to 60 drops three times a day. In addition, arsenic and glycerophosphates were administered from time to time. The nose was kept flushed with glycothymolin and hot baths with carbonate of soda at 95° F. were given twice a day. In July, 1903, the patient was free of any leprosy lesion, bacteriological examinations of secretions and urine proved negative. Up to the present time the patient has been bacteriologically examined three times with negative results. There has been no recurrence of the disease.

Case IX.—J. C., aged thirteen years. This boy has been the subject of widespread newspaper report because of his discharge from the Louisiana Leper Home. He was admitted in 1902 as a typical case of tuberculous leprosy. His treatment consisted in 1-60-grain doses of strychnine sulphate and chaulmoogra oil up to 100 minims at the dose. His improvement began promptly, and, at the end of one year, the tubercles had disappeared. In June, 1904, there were some small areas of pigmentation left. In December, 1904, after negative bacteriological examination, and the lack of any evidence whatsoever of the disease, the boy was discharged. He is still kept under observation and up to the present time remains well.

Case X.—S. J., aged thirty-eight years; native of New Orleans. First seen March 30, 1898. Typical tuberculous leprosy involving face, hands, legs and back. The patient persistently improved under chaulmoogra oil and strychnine, never reaching more than 40 drops of the oil. She has been free of any evidence of the disease since 1903.

The Louisiana Leper Home might have afforded wide opportunity of sucessful therapeutic investigation were it not for the fact that the policy of the Board of Control, after I resigned in 1896, directed the Leper Home as more of an asylum than a hospital. As a result, during the

"*Notes.*—It has been supposed that the source of chaulmoogra oil is *Gynocardia odorata*, R. Browne, or *G. Prainii*, Desprez; but neither of these plants appears to produce the chaulmoogra seeds of commerce, from which the oil is obtained. The chief constituent and active principle of the oil is gynocardic acid, which causes the coloration produced on mixing the oil with sulphuric acid. The oil contains gynocardic and palmitic acids, both in the free state and as glycerides, while the glycerides of hypogaeic and cocinic acids are also present. Gynocardic acid can be obtained in crystalline plates and has an acrid, burning taste."

"As you will note from the above quotations, the true source of chaulmoogra oil has been uncertain till within very recent times. The quotation from the *Pharmaceutical Journal* of Sept. 14, 1901, above cited, is probably the most reliable summing up of the facts in the case. The statements there made as regards physical properties and chemical tests are characteristic of the oil which we handle, and which we import direct from India. As you will note from the facts above quoted, there is a slight difference between the oil as prepared by the more or less crude, native process of expression and that prepared by the more modern, scientific methods of expression by solvents. The latter oil prepared by the solvent process is most likely to be obtained from European sources, where such plants for the economical extraction of vegetable oils are located; on the other hand, *the oil obtained from India is most likely to be made by the old-foshioned process, and we have continued to obtain our oil from East Indian sources, as it is upon such expressed oil that the reputation of this remedy is based. You will understand that we are not prepared to state that the highly refined oil prepared by the solvent process in Europe is not entirely as good as the crude oil made by the natives in India, but, so long as this has not been demonstrated by actual clinical tests, we have thought it advisable to stick to the Indian supply.*

"We are very sorry, indeed, that we have not been able to offer you more detailed information as to the native method of manufacture, but, as you see from the above quotations, about the only fact apparent is that the native process consists in grinding or crushing the seeds and then submitting them to expression. If there are any further facts relating to this subject upon which you think we can possibly throw any light, we shall be very glad to receive some further communication from you.

With best wishes, we remain, Yours very truly,
(Signed.) PARKE, DAVIS & CO.,
Per J. M. F.

years 1896-1902, no specific treatment was applied to the inmates of the Home, and they were allowed to fulfil the natural outcome of the disease. Since 1902, regular systematic treatment has been adopted with the result that marked amelioration has been obtained in every case not too far gone. Dr. Ralph Hopkins, my chief of clinic in the Tulane Medical Department, and clinical assistant in the New Orleans Polyclinic, has systematic charge of the Home, and it is to his care and judgment that whatever results that have been obtained are due. Analysis of his very able report embodied in the last report of the Louisiana Leper Home (1904) to the Louisiana State Legislature, clearly evidences what results have been obtained. In the 40 odd cases treated a variety of remedial agents were employed. Of these the most effective were chaulmoogra oil, strychnine and salicylate of soda. The red mangrove, normal horse serum and miscellaneous agents experimented with proved of little avail.

It is to be remarked that almost all patients taking chaulmoogra oil have improved.

Of the present inmates in the Home there are fully a half dozen who have improved to the point of certain arrest in the disease; two of them being now kept under observation with the idea of their discharge at no far distant date.

So much newspaper notoriety has attached to my work with leprosy that I have considered it a privilege to present this whole subject before the association of medical men in my native State of Texas. I am not alone in believing leprosy curable and can cite such men as Fox, Unna, Crocker, Hutchinson, as among those who have cured the disease and who have recorded their work in this direction. I believe that no such number has as yet been recorded as those given above by me. Mr. J. F. Tonkin, officially representing the British government, reports upon the conditions in Jamaica in his report for 1903, and states that since the Kingston Leper Hospital was instituted a total of sixteen cases have been discharged.

I cannot conclude this paper without referring to the able contributions to this subject by another Texan, Dr. R. H. L. Bibb, now located at Saltillo, Mexico. Besides having written the most exhaustive paper yet published on the treatment of the disease (Alvarenga Prize Essay for 1905) he has emphatically declared himself in believing that chaulmoogra oil is the specific for leprosy.

It may be some time before the majority of the profession can be persuaded to the precept which this article conveys, but if I have succeeded in stimulating a discussion, contrary or otherwise, I shall be satisfied that the work embodied has not been in vain.

Medical Consultations in China.—Medical consultations are carried to their extreme limit in China. There, when any one becomes seriously ill, a consultation of 15 or 20 doctors is held. The doctors fill the house with their arguments. They make as much noise as a political convention.

PRIMARY SARCOMA OF THE STOMACH.[1]

BY MORRIS MANGES, M.D.,
OF NEW YORK;
PROFESSOR CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO MOUNT SINAI HOSPITAL, NEW YORK.

Although it is true that sarcomata must be included among the rare tumors of the stomach, yet recent studies have demonstrated that they may possibly occur more frequently than is generally supposed. Fenwick is probably not far from the truth in his assertion that they constitute from 5 per cent. to 8 per cent. of all gastric tumors. In proof of his claim he urges that the greater number of cases has been reported since attention was especially called to their occurrence by Virchow, forty years ago, and that the re-examination of some specimens which had been catalogued as gastric cancer has demonstrated that the tumors were really sarcomata. Furthermore, that although Schlesinger was able to collect only 30 cases in 1897, yet in November, 1900, the number of cases exceeded 60. Rosenheim also states that sarcomata are not as rare as is supposed. Perry and Shaw found 4 cases of sarcoma in 50 cases of malignant disease of the stomach; Haberkahndt found 3 sarcomata in 207 pyloric resections; while Czerny found only 2 sarcomata in 208 gastro-enterostomies.

The two cases which I shall report occurred within one year at the Mt. Sinai Hospital. Dr. Harlow Brooks informs me that in addition to the case which he published in 1898 he has since been able to collect 3 additional cases during nine years' service at Bellevue Hospital.

That uncollected cases may be scattered through the literature was strikingly shown to me recently when, while hunting up a false reference in the transactions of the London Pathological Society, 1889, I found an unreported case of diffuse gastric sarcoma.

On the other hand, Alesandri, whose article is one of the most recent on the subject, still maintains that they are very rare. This question is of interest, not so much from a diagnostic and pathological standpoint, as to that of prognosis, since the results of operation in some cases of sarcoma are decidedly better than in carcinoma as is well shown in Dock's case in which a large lymphosarcoma was removed over four years ago. I have learned from a recent personal communication from Prof. Dock that the patient is still alive and well. It is possible, therefore, that in the absence of more definite pathological details on the subject, some of our observations on the operative results of carcinoma of the stomach may be modified.

To consider many of the details of the pathology, symptomatology, etc., is scarcely necessary, since much of it would be a useless repetition of what has already been well presented by Schlesinger, Fenwick, Alesandri and other writers.

---

[1] Read at the Eighth Annual Meeting of the American Gastro-Enterological Association, held at New York, April 24 and 25, 1905.

Here it will suffice to call particular attention to certain practical features:

1. That the new growth arises from the submucosa or muscularis, the mucous membrane being involved only late in the disease as a secondary result, or it may escape entirely. The curvatures, especially the greater, are usually involved, the pylorus being less frequently attacked.

2. The growth may be diffuse, as usually occurs in lymphosarcoma, or it may be circumscribed, this being the ordinary form of the spindle-celled type. These circumscribed growths often assume a polypoid form, growing either into the lumen of the stomach, or outwardly into the greater or lesser peritoneal cavity. These polypoid tumors constitute a very puzzling group, the diagnosis of which is exceedingly difficult, since it is in these cases that the mucous membrane is usually intact while few if any of the symptoms draw attention to the stomach as being the real source of the neoplasm.

3. The orifices are rarely stenosed and if the pylorus is involved the stenosis never reaches the degree so frequently encountered in carcinoma.

4. Degenerations frequently occur in these tumors. These include hemorrhages, cystic degeneration, formations of fistulous tracts, etc. On the other hand, it is to be noted that sometimes the sarcomata are themselves degenerations of other benign tumors such as fibromata, myomata, etc.

5. As regards size, they may constitute large tumors (weighing 12 pounds or more), or they may be so small as to be found only by mere chance at autopsy.

6. They may be primary or secondary. The latter are the rare forms, except in lymphosarcoma where the secondary forms are commoner than the primary. Doubt has even been cast upon the cases of primary lymphosarcoma since it is urged that some small, primary lymph-gland tumor may have escaped notice. These secondary lymphosarcomata are usually derived from some growth in the neck, pharynx, gums, rectum, retroperitoneal sarcoma, etc., or they may constitute part of a general lymphosarcomatosis of the gastro-intestinal tract, or they may be an internal manifestation of Hodgkin's disease.

7. Metastases may occur in neighboring or distant organs, or they may be absent. The distant organs may include the skin, testicles, tongue, tonsils, rectum, etc. The skin metastases are of particular interest since their occurrence is much more frequent than in cancer and may thus afford much important diagnostic information.

8. *Age.*—The range is very great. Finlayson's case occurred at 3½ years and the case of Malvoz occurred at seventy-eight. Fleiner states that they may even be congenital. As a rule the average age is younger than in carcinoma; thus the 4 cases of lypmhosarcoma reported by Perry and Shaw were fifteen, eighteen, thirty-eight and sixty-seven years old.

Special attention may be directed to a group of cases with gastric symptoms in which hematemesis is the leading symptom. Although it has been shown that bleeding is a relatively infrequent symptom in gastric sarcoma and is used as one of the points of differential diagnosis, yet cases have been reported in which the bleeding was either an early or a late symptom and even led to that mistaken diagnosis of gastric ulcer.

One of the earliest cases with hematemesis is that of Hartley to whom I am indebted for the following report:[1]

Mrs. B., fifty-four years. Five years ago (1890), without any special cause, she vomited a large amount of coffee-ground material. The vomiting did not recur and she went on for four years in fair health, except for the heavy feeling after eating. One year ago she again vomited blood of coffee grounds and clotted in character for five mornings in succession; this was again without cause or exacerbation of gastric symptoms. The pain in the back which she had suffered previously became much worse at this time and she noticed a considerable swelling of the stomach.

Physical Examination.—In the left lumbar and left umbilical region is a rounded tumor about the size of the adult fist, which is hard and elastic, freely movable and easily displaced up into the left hypochrondriac region.

Operation.—April 26, 1895. Incision 5 in. long, just to the left of the left rectus; the hand was introduced and prolonged search made. The kidney could be felt in place, the large intestine bulged into the wound and was normal; behind the mesocolon and in what appeared to be the position of the spleen was the large tumor; the spleen was not felt. The mesocolon was torn through and the surface of a tumor in lesser peritoneal sac disclosed. This tumor was brought through this opening in the mesocolon and it was seen that it arose from the posterior wall of the stomach by a pedicle 1½ in. in diameter. The stomach was pulled well out and graped by house surgeon well below the pedicle. The stomach was now cut through entirely around the pedicle and a circular part of stomach wall excised. Abdominal wound closed in usual manner with drainage in center.

Pathological Report.—By Dr. Ferguson, May 10, 1895. The material is a pear-shaped tumor measuring 15 x 10 x 8 cm. Its surface is smooth but nodular. It is apparently covered by peritoneum. The tumor is cystic, the cysts varying in size from ½ to 4 cm. in diameter. The tumor is firm in consistency and of pale gray color. An area of stomach wall 5 x 4 cm. has been removed with the tumor, the mucosa has not been ulcerated but is intensely hyperemic. Sections show the ordinary appearance of spindle-celled sarcoma. The vascular supply is abundant, some of the vessels being large with thin walls.

1 This is the case which was published in the Annals of Surgery, 1806, Vol. 23, p. 609.

Discharged cured, June 1, 1895.

Case II, which I present, was also marked at its close by severe hemorrhages from the stomach and bowels.

Oberst has just published a paper in which he directs especial attention to this group of cases; he reports a case of gastric sarcoma (man, twenty-five years old) which was mistaken for a gastric ulcer. He also quotes a similar case of Robert and two of Kundrat. He therefore urges that the possibility of gastric sarcoma should be considered in youthful individuals with hematemesis in which the course is unusual or in which there is delayed convalescence after hemorrhage of the stomach.

Symptoms.—The cases may be divided into two great groups: First, those without; and second, those with gastric symptoms.

In the first group are included the cases in which the tumor grows outwardly into the peritoneal cavity and also many of the cases in which the growth is toward the gastric lumen but in which the infiltration of the stomach does not involve the pylorus and leaves the mucous membrane intact. This group includes the unusual cases of abdominal tumors which have been incorrectly diagnosticated, the true condition being revealed at operation or at autopsy.

The complications from the peculiarity of the growth may dominate the picture, such as adhesions, torsions, displacements, hemorrhage in the tumor, cystic degeneration, suppuration, etc., or, metastases may cause leading symptoms such as disturbances in the intestines, rectum, etc. One peculiarity of the intestinal metastases is to be noted—that they rarely cause stenosis, being thus unlike the secondary growths which occur in gastric carcinoma in which stenoses may much more frequently occur.

In the second group the gastric symptoms are practically those of gastric cancer. In most cases, however, the gastric symptoms are mild and only become marked toward the end of the patient's life.

A few points of differentiation may be noted. That vomiting and hemorrhage are less frequent and are usually only late symptoms. On the other hand, pain, fever, albuminuria, marked anemia and weakness are more marked and occur much earlier; indeed, the marked anemia and weakness may for a long time be the only symptoms. The appetite may fail, or, as in gastric cancer, may persist throughout. Perforation occurs more frequently. Marked splenic enlargement is much more frequently noted than in gastric cancer. On the other hand, omental and peritoneal involvement are less common. The skin metastases have already been referred to. A number of other minor conditions have been reported, still they are too inconstant to be of great differential diagnostic value.

The physical signs are inconstant as is readily understood from what has already been said concerning the pathology. Fenwick states that tumor was present in only 30 per cent. of the cases, and when the tumor was present it was frequently mistaken for tumor of the spleen, of the pancreas, kidney, omentum, ovary or retroperitoneal glands.

There are great variations in the size of the stomach since it may be enlarged or contracted or displaced or distorted, as occurs in the unusual cases where there is marked downward displacement of the stomach which is at the same time distorted into a sausage-shape resembling the transverse colon.

The stomach contents have been observed in about ten cases. They are practically identical with those found in cancer of the stomach. In one of the cases which I report the same is to be noted. In one case which was under observation Erlach could follow the transition from normal chemism to complete absence of hydrochloric acid which occurred later in the disease. In several cases there was no change in the gastric secretion. Indeed, considering how long the mucous membrane remains uninvolved it is surprising that there is as much change in the chemism of the stomach as has been reported.

The stagnation in the stomach contents is not due so much to pyloric obstruction in these cases as it is to the infiltration of the muscularis.

Diagnosis.—The possibilities of diagnosis are best summed up in the words of Leube who has allowed them to remain unchanged even in the recently published edition of the *Diagnostik:* "In my opinion these tumors *cannot be diagnosticated*, not even when the conditions are very favorable for making a clever diagnosis, because of of the presence of a general sarcomatosis or cutaneous sarcomata. In one such case, it is true, I found a gastric sarcoma, but in another case of skin sarcomatosis the tumor in the stomach was a true epithelial cancer." However, if more exact points of differentiation are desired, I may quote the differentiating points given by Fenwick, who claims that "a diagnosis of round-celled sarcoma of the stomach may often be made by attention to the following points:

1. The disease usually occurs before thirty-five years of age, so that the younger the patient the greater the probability that the malignant affection is sarcomatous in character.

2. In many cases there is slight but continuous pyrexia, accompanied by rapid and profound anemia, while in carcinoma fever is usually absent during the early stages of the complaint and the cachexia much more gradual in its development.

3. Enlargement of the spleen is by no means infrequent but is rarely met with in cancer unless the organ is involved in the growth.

4. According to Kundrat the tonsils are apt to enlarge and the follicles upon the sides of the tongue may become swollen or ulcerated.

5. Secondary deposits in the skin occur in a notable proportion of the cases and permit of excision and microscopic examination. It should

be remembered, however, that sarcomatosis has been met with in true cancer of the stomach (Leube).

6. A large nodular tumor due to infiltration of the omentum and a greatly enlarged liver with secondary growths in its substance are rarely met with.

7. Persistent albuminuria is often observed in sarcoma but is exceptional in cancer.

8. The discovery of pieces of morbid growth in the vomit renders the diagnosis certain. (Riegel, Westphalen).[1]

Prognosis.—As already stated, this in some cases is decidedly better than a carcinoma; in other cases, however, the course may even be more malignant.

Treatment.—If the diagnosis has been made arsenic ought to be used as it is in all cases of lymphosarcomatosis, otherwise the treatment is strictly surgical.

The histories of the two cases I present are as follows:

Case I.—L. S., shoemaker, forty-eight years of age, was admitted to Mt. Sinai Hospital to the service of Dr. Alfred Meyer, September 26, 1903. His symptoms are of four months' duration—loss of appetite, occasional vomiting of food, obstinate constipation. He has lost considerable flesh and strength. General condition fairly good; tongue moist, coated; a few small glands in the neck, axilla and groin. Physical examination negative throughout. Abdomen lax, tympanitic, no tenderness, no tumor palpable; general visible peristalsis. No fever. Urine negative. September 27—Test breakfast (Ewald).—Slightly digested; total acidity 40 per cent.; free hydrochloric acid absent; combined acids 30 per cent.; no lactic acid. Ferments absent.

September 30—Total acidity 84 per cent.; free hydrochloric acid absent; combined acids 26 per cent.; lactic acid present; no blood. Ferments absent.

He left the hospital October 2 very much improved. He was readmitted on December 7. For ten weeks previous to his readmission he had had fever, pain in the upper right quadrant of the abdomen, the pain having no relation to the ingestion of food. Eructation and cardiac palpitation after eating. Progressive loss of flesh and strength. Vomited only once; no blood. Defecation and urination normal. Chief complaint abdominal pain and weakness.

Physical Examination.—Mucous membranes pale; pupils unequal, the left being somewhat larger than the right. Abdomen: The veins on both sides of the lower abdomen dilated. Liver extends to three fingers below the free border In the right hypochondriac region a large mass, somewhat irregular in shape, with a sharp edge can be felt; it extends on the right to the mammillary line, on the left it reaches one-half inch to the left of the middle line; its lower border is within one-half inch of the umbilicus; it is dull tympanitic on percussion and not tender; otherwise the abdomen is negative. Urine negative.

Blood Examination.—Thirty per cent. hemoglobin; red blood cells, 4,000,000; white, 13,600.

Test Breakfast (Ewald).Two ounces removed; fairly digested; total acidity 26 per cent.; free hydrochloric acid absent; lactic acid present; ferment absent.

December 10—The patient vomited a very large amount of undigested food. The mass became much more prominent after this and extended from the right mammillary line to the left parasternal line, above it reached the free border of the ribs, on the right of the mammillary line, midway between the umbilicus and the xiphoid was a sharp edge. Dull tympany over the tumor.

December 12—Movable dulness in both flanks, fluid in the abdomen. The patient is now running a slight evening temperature. The urine now contains a faint trace of albumin. For the past few days he has had three to four stools daily.

Consent having been obtained for an operation he was transferred to Dr. Gerster's service where a gastro-enterostomy was performed on December 14. Death three days later.

Autopsy seventeen hours after death by Dr. Libman.

Murphy button found at site of gastro-enterostomy, good apposition of stomach wall and jejunum.

Lungs.—Right upper lobe was in incomplete gray hepatization. Both lungs adherent; markedly anthracotic. Pleura showed a moderate number of hard thickenings, some flat, some nodular. Acute pulmonary edema.

Stomach.—Moderately dilated. At pylorus a large, hard nodular tumor adherent to pancreas and duodenum and involving the whole circumference of the stomach for a distance of 3 inches from pylorus. Parts of the tumor were soft and had undergone degeneration. Pylorus admitted one finger. The interior of the stomach showed the same tumor ulcerated and involving the pylorus and stomach but not the duodenum. In other areas of the stomach wall there were some small hemorrhages in the mucosa.

Liver.—Normal size and consistency. Cloudy swelling (no metastases).

Kidneys.—Capsule of the right adherent. Both acutely degenerated.

Microscopic examination of the gastric tumor proved it to be a lymphosarcoma.

Case II.—Mrs. A. S., forty-eight years of age, admitted to Mt. Sinai Hospital, under the care of Dr. Albert Kohn, August 6, 1904. For years this patient had had repeated uterine hemorrhages, supposedly due to fibroids, for which, however, she had refused operation. Not long before she came under treatment she had several uterine hemorrhages and her intense anemia was supposed to be due to that cause.

She was first seen July 3 with the symptoms of a marked secondary anemia, confirmed by several

[1] Schlesinger made the diagnosis in one of the cases from a piece excised from a metastatic mass in the rectum.

blood examinations. Loss of flesh and strength were not marked. Complaints were of extreme dizziness, sinking sensations, inability to assume the upright position. Headaches general. Loss of appetite, nausea, eructations. Vomiting only once or twice. She had many movements (9 to 12 daily) which were very loose, tarry and controlled with difficulty. Tenderness over the entire abdomen with pain, both marked over an epigastric tumor which was the size of a peach. The tumor was freely movable and did not disappear under the ribs. Her temperature was never above 101.5° F.; never subnormal.

Blood Examination.—Hemoglobin 18 per cent.; red cells 1,590,000. A few poikilocytes and microcytes; granular degeneration of red cells; moderate relative leucocytosis. Stools contain pus and red blood-cells. Hemin test positive. Urine 1.010, large trace of albumin; no tubercle bacilli.

The diarrhea, loss of appetite, nausea, eructation and obstinate loose, watery stools with small blackish fecal particles, the increasing anemia and abdominal pain and tenderness were the only symptoms. During observation at the hospital the most prominent symptoms were sighing respiration and weakness, diarrhea and vomiting, melena and bloody vomit. The physical examination showed not only a mass in the epigastrium, but two masses, one in each iliac fossa which were apparently new growths. However, on post-mortem examination nothing could be found to account for these two tumors. Test-meals could not be given on account of the wretched condition of the patient. She died August 13, 1904.

Autopsy.—By Dr. Buerger. *Lungs.*—Congested at base; few pleural adhesions. *Liver.*—Grayish-brown color, pale, firm consistency; marked parenchymatous degeneration, pigmentation, slightly fatty. *Stomach.*—Externally negative except for a somewhat depressed, scar-like area, 4 cm. proximal to pylorus, in the immediate neighborhood of which are stellate dilated vessels. Capacity somewhat increased; wall slightly thinned. About 4 cm. from the pylorus on the anterior wall there is a soft grayish-pink flattened sessile tumor, almost circular in outline, raised by a rounded though irregularly lobulated convex surface 12 mm. above the surounding mucosa. It appears even less prominent than this owing to a very marked, raised, somewhat circular, well-defined margin of slightly cicatrized mucosa immediately surrounding it. At one portion it is ulcerated and excavated so as to be on a deeper level than the mucosa of the stomach. Upon section it presents a radiate, irregular, streaky surface, here and there beset by small hemorrhages.

Microscopic examination shows it to be a myosarcoma. Intestines practically negative except for the presence of altered blood. In the ileum there are several script-like areas of brown pigmentation. No ulcerated areas or any points of bleeding could be found. Uterus contains small submucous fibromata. Bone marrow red in color, soft, diminution of fatty elements. Kidneys, intense parenchymatous degeneration. Interstitial changes in medulla. Spleen congested.

LITERATURE.

The literature of sarcoma of the stomach may be found in the following references which include the most important contributions to this subject.

CYSTIC KIDNEY AND LIVER.[1]

BY HERMAN A. REQUE, A.B.,

OF CHICAGO, ILL.

THE cases which I wish to discuss belong chiefly to that form of cystic kidney in which there is a total cystic degeneration of the organ and, usually, a great increase in its size. This form has also other features which seem to differentiate it from the ordinary retention cysts sometimes found in chronic nephritis and from the so-called solitary cysts. Some of its peculiar features are the following: (1) It is generally bilateral; (2) it often occurs with cysts of the liver or other organs; (3) it is often, according to some authorities, always, congenital; (4) it is sometimes associated with malformations, as polydactylism, webbed toes, cleft palate, hydrocephalus, anomalies of the genitalia, etc.; (5) it has been found in several members of the same family; (6) it presents microscopic appearances, in many cases, which are difficult to explain by any purely inflammatory or retention theory.

It is not to be inferred that all cases presenting any of these features necessarily have the same origin, but they are often grouped together under various names, as cystic kidney proper, congenital cystic kidney, polycystic degeneration of the kidney, or the gros rein polykystique of the French.

Several specimens and records of such cases exist in the pathological laboratory of Rush College and form the basis of this report. Two of the cases are accompanied by cystic degeneration of the liver.

Before going on to describe these cases I will attempt to give a brief résumé of some of the most important recent literature on this subject as well as briefly to mention the different theories of origin of cystic kidney and liver that have been advanced. A concise consideration of the whole subject is found in an article by Hektoen, written in 1892; of more recent ones that by Dunger is especially noteworthy and gives a complete bibliography up to date.

Virchow noted the occurrence of cystic kidneys in several children of the same mother and was inclined to explain them as due to some

1 From the Pathological Laboratory of Rush Medical College, Chicago.

inflammation occurring in utero, depending on some product derived from the maternal organism, and involving especially the papillæ so as to cause an occlusion of the discharging tubules —a papillary atresia. This view represents one form of the retention theory. Cystic kidney in the adult Virchow thought to be simply the remains of a condition developed in fetal life.

The retention theory was supported among others by Thorn, who thought that an inflammation of the renal pelvis with involvement of the medulla was probably a frequent cause. Durlach describes a case in a child of six months, where a primary pyelitis had produced cysts. Arnold has described an interstitial papillitis. Leichtenstern expresses the view that the same processes which ordinarily set up an interstitial nephritis may, under certain circumstances, affect chiefly the arteriolæ rectæ veræ and thus cause a primary nephropapillitis, resulting in the occlusion of single tubules and the formation of retention cysts. Ewald and others adopt one of Virchow's earlier views and make a precipitation of uric acid or other substances in the tubules responsible for the cyst formation. This is again a form of the retention theory. More recently, Stieda described a case in a woman twenty-seven years old of bilateral cystic kidney "*in statu nascendi.*" In this case the cysts were small and the organs very moderately enlarged. There was no evidence of any epithelial proliferation nor of any very recent inflammation. But there were present disseminated foci of scar tissue, probably due, the author thinks, to some past, rather acute inflammatory process, perhaps a pyelonephritis. Closure of the tubules by these foci of scar tissue he thinks to be the cause of the cysts, which would then be retention cysts pure and simple. Whether this past inflammatory process would be capable of carrying on the cyst formation to the stage of a total polycystic degeneration is another question. As bearing on this point, an experiment by Tollens may have some interest. It is well known that ligation of the ureter causes atrophy of the kidney. More closely to reproduce the conditions found in a nephropapillitis, the kidneys of rabbits were exposed and opened by longitudinal incisions and the papillæ then cauterized so as to close effectually all ducts in the papillæ so treated. The kidneys were removed and examined after intervals of 4, 8½ and 12 weeks. After four weeks the kidneys were found to be double their normal size and full of minute cysts formed by dilatation of tubules. In the papillæ all the tubules were closed by scar tissue. Some of the tubules affected showed several layers of epithelium and other apparent efforts at regeneration or proliferation. There was a great proliferation of connective tissue. The kidneys examined after 8½ weeks were much smaller than normal. The obstructed tubules showed in part increased dilatation, in part total compression, while some had again found an outlet into the pelvis. These changes were still more pronounced after twelve weeks. Considerable connective tissue remained and became sclerotic. Some cysts also remained. But the general conclusion drawn by Tollens is that the closure of the excretory ducts, where it is permanent, in the kidney as in other glandular organs, simply results in destruction of the parenchyma, which is replaced by scar tissue. It seems to me that this experiment would tend to show that a past inflammatory process does not result in cystic degeneration in the narrower sense. It does not appear from the original article whether the author intended to prove or disprove any theories as to cystic kidney.

That such processes as those mentioned can and do produce cysts in the kidney, both bilateral and unilateral, seems certain; but many of the cases so explained would probably belong with the ordinary retention cysts of chronic nephritis.

Still calls attention to the fact that cystic kidney is more frequent in the female than in the male, in the proportion of four to one, while interstitial nephritis is more frequent in the male in the proportion of five to one.

A second theory, supported by many recent investigators, is the cyst-adenoma theory. As early as 1876, Michaelowicz suggested that "cystic degeneration of the kidney is analogous to cystic disease of the testicle, mammary gland and ovary." Brigidi and Severi describe a case of bilateral cystic kidney as true tumor formation —cystoma of the kidney. Chotinsky thinks that proliferation of the epithelium precedes the cyst formation and may be a cause of the same by obstructing the tubules and causing retention of the secretions. Orth suggests that adenomatous cysts with a primary proliferation of the epithelium may have to be differentiated from retention cysts with a passive condition of the epithelium, especially in those cases where cysts of the liver are also present. Lejars describes the process as a mucoid epithelioma similar to that of the testicle and ovary. Sabourin expresses the view that the cysts have their origin in a special evolution of the urinary tubules, the epithelium of which has been reduced to an indifferent state by cirrhotic processes and then later forms alveoli and nodules which develop into cysts. This view is pronounced by Dunger to be far-fetched. Philippson describes solid epithelial processes in the tubules as possible factors in cyst formation. He also found papillary growths covered by epithelium extending into the cysts.

One of the most important contributions to the cyst adenoma theory is that of Nauwerck and Hufschmied. These investigators found much evidence of inflammation, especially a great proliferation of connective tissue; but they lay more stress on the evidences of epithelial proliferation. They found solid epithelial processes extending from the tubules and pushing out through the basement membrane; solid masses

of epithelial cells within the tubules; papillary projections of fibrous tissue covered by epithelium extending into cysts; small cysts lined by several layers of epithelium. From these findings they conclude that their specimen represents a multilocular cystadenoma. As factors in the further growth of the cysts they consider decomposition of leucocytes, colloid degeneration of the proliferated epithelium, exudation or transudation, and retention of secretions.

Von Kahlden corroborates the above findings. He saw solid masses of deeply staining cells projecting from the tubules; some of these cell-masses showed a beginning central degeneration, and he was able to follow this change to the stage of cyst formation. He regards the interstitial changes as secondary. The retention theory he considers inadequate, not only in view of the histologic findings, but also in view of the frequent complication with other maldevelopments, as cystic liver, which was present in one of his cases. Cystic kidney in the adult, he thinks, may be congenital and, not being far advanced at birth, may remain latent for many years. The same author describes also a case of cystic kidney in a new-born child. The right kidney was four times its normal size, the left not so much enlarged. The cortex in both was full of small cysts. In this specimen he found the same epithelial proliferation and cyst development from masses of epithelium. The number of glomeruli was reduced to about one-eighth of the normal and there were practically no normal tubules. On the whole, the process was decidedly cystadenomatous, although in places, owing to the great amount of fibrous tissue, it resembled a fibro-adenoma canaliculare.

In view of these investigations it seems certain that the cyst-adenoma theory will explain some cases both in the new-born and in the adult, the main difference between the two being that in the latter the cysts have grown larger and secondary inflammatory changes may have occurred.

A third theory of the origin of cystic kidney remains to be spoken of, the malformation theory. To appreciate the bearing of this theory it is necessary to have in mind the embryological development of the kidney. According to the most widely accepted view, two elements are concerned. On the one hand, the medullary portion, comprising the whole collecting and discharging system of the permanent kidney (metanephros), is formed from a diverticulum of the Wolffian duct, which is developed at a point just above the place where the duct empties into the cloaca. The researches of Schreiner and others on this point seem to be conclusive. The cortical portion, on the other hand, comprising the secretory system (glomeruli and convoluted tubules), is formed from the nephrotome or "nephrogenic tissue" (Schreiner), and later comes into communication with the branches of the diverticulum from the Woffian duct. It appears, therefore, that the permanent kidney is formed from the same material as the primitive kidney or mesonephros, which also has a dual origin, in part from a series of diverticula from the Wolffian duct at a higher level (more cephalad) than the special diverticulum of the metanephros, in part from the nephrogenic tissue. While the metanephros reaches its full development the mesonephros atrophies or is utilized in the building of other structures.

Most of the adherents of the malformation theory have explained the kidney cysts either as arising from actively secreting mesonephric elements which have failed to atrophy and have been incorporated in the permanent kidney, or as being due to a failure of union of some of the secretory and the collecting or excretory elements of the permanent kidney. The former view has been supported by Shattock, Sutton and others; but in view of the fact that the meso- and metanephros are homodynamic organs, according to Schreiner and others, it would seem to be impossible to identify any mesonephric rests if they should occur in the kidney, unless by some extraordinary good fortune a specimen could be secured of a particular stage of intrauterine development, in which this abnormality was being developed. The second view has found many supporters. Thus Ribbert found in some areas of cystic kidney tissue glomerular and tubular cysts, but no convoluted tubules. Rückert applies the malformation theory to unilateral as well as bilateral cystic kidneys in the adult as well as in the new-born.

The most recent important contribution to the subject of cystic kidney and liver is the previously-mentioned article by Dunger. This writer supports the malformation theory and lays special stress on an etiological factor which he thinks plays an important part, the hereditary predisposition. He describes two cases of cystic kidney occurring in the same family, in mother and daughter, the immediate cause of death in both being cerebral apoplexy. In both cases the gross and minute changes were about the same and corresponded pretty closely to what had been observed by Nauwerck and Hufschmied, Von Kahlden and others, and explained by them as cases of cystadenoma. Dunger also speaks of the clinical symptoms and the difficulty of diagnosis, which has been made only nine times. He thinks the family history may sometimes aid in the diagnosis. He finds twelve instances on record of cystic kidney occurring in two generations, which is a considerable number considering the rarity of this disease. Its occurrence in two or more children of the same parents is more frequent. Some of the most remarkable instances mentioned by Dunger are the following: Virchow's case of four children of the same mother; a case of five children of the same mother; a case in which father, son and a nephew were affected, another nephew having a double thumb; a case in which father,

son, and a sister were affected, some of the other children also having symptoms of the disease; another case like the preceding except that two sisters of the father were affected.

Dunger's most important conclusions are as follows: (1) Cystic kidney is always congenital, also when we find it in adults. At times it may be so far advanced in utero that the child cannot be delivered normally, or dies early; at times it may not reach any great development until late in life. (2) The association with other malformations and the hereditary tendency support the malformation theory. (3) The most likely explanation is either a failure of union between the two elements concerned in the development of the kidney, or an incoordinate development of mesoblast and hypoblast, as suggested by Borst. Further to illustrate his views Dunger describes two cases of cystic kidney occurring in infants. In the first, the glomeruli seemed to communicate directly with the collecting tubules, there being no evidence of convoluted or looped tubules. (This reminds us of Ribbert's case.) There was no evidence of any inflammatory or neoplastic process, and Dunger cites this as a case of cysts due simply to a maldevelopment. In this case there were also cysts of the liver, evidently due to a proliferation of bile-duct epithelium.

In the second case, there was also no abnormal proliferation of epithelium. There was a great excess of connective tissue, but Dunger does not regard this as excluding the malformation theory. The number of tubules, especially of collecting tubules, was much reduced, but glomeruli were found everywhere. Some tubules were found to have a blind ending. A great many of the cysts contained normal glomeruli. Dunger considers this case as similar in many respects to those described by Virchow as a papillary atresia, but interprets some of the findings as evidences of a malformation.

From a review of these different cases and theories advanced to explain them it seems evident that not all cases presenting the macroscopical appearances of so-called "cystic degeneration" or "gros rein polykystique" can be explained by any one of the theories advanced. This seems, however, to have been attempted. Thus the adherents of the cystadenoma theory have claimed that the inflammatory processes, *i.e.*, connective tissue proliferation, etc., when present, are secondary to an abnormal proliferation of epithelium, and the adherents of the malformation theory have considered the excess both of connective tissue and epithelial growths, when present, as secondary to or indeed as constituting a part of a maldevelopment.

Evidences of inflammatory processes which might lead to the formation of retention cysts have not been found in all cases; epithelial growths suggestive of cystadenoma have not been uniformly present; direct evidences of any maldevelopment have been found only by a few observers, perhaps because they are so easily overlooked; possibly this last theory might be the correct one in many cases. The hereditary factor has been made to harmonize with all of the three principal theories; certainly, heredity may predispose to inflammatory processes, to neoplasms, and to malformations. In short, each of the different theories seems to have found cases which admirably illustrate and justify it, while some cases present such a variety of appearances that they may be pressed into service by the adherents of quite opposite theories with equal advantage.

In regard to cysts of the liver the literature is more scant, perhaps because the process of their origin seems to be simpler or because fewer cases have been found. The cysts, except the largest ones, have generally been found to be lined by an epithelium of short, cuboidal cells like those of the bile ducts. At the same time there has been found an active proliferation of bile-ducts, and the cysts have been thought to be formed by a dilatation of the proliferated bile-ducts; in fact, the gradual transition of these bile ducts into cysts has been pretty definitely traced. Nauwerck and Hufschmied, among others, consider the process as cystadenomatous. The bile ducts proliferate chiefly interlobularly, but tend also to invade and replace the lobules. They are usually surrounded by a great deal of fibrous connective tissue, which some have considered as evidence of a true cirrhosis, while others have considered it as arising secondarily to, or coordinately with, the epithelial proliferation.

As to the etiology of these cysts we are, as in the case of the kidney, confronted by three chief theories: (1) The inflammatory theory. In objection to this theory it is urged by Still and others that neither in biliary cirrhosis nor in congenital obstruction of the larger ducts is there any proliferation of bile ducts with cyst formation. On the other hand, there is no jaundice in cystic liver, and no bile was found in the cysts by Still, Nauwerck and Hufschmied, or Von Kahlden. (2) The new formation theory, already mentioned. (3) The developmental or malformation theory, which is generally credited to Still. The excretory part of the liver is developed from a diverticulum of the intestine somewhat in the same manner as the corresponding part of the kidney is developed from a diverticulum of the Wolffian duct. Still assumes that some of the branches of the liver diverticulum fail to become differentiated into bile-ducts and, persisting, develop into cysts, surrounded by masses of fibrous tissue derived from mesoblast which failed to become properly differentiated into secretory, vascular and interstitial tissues.

Borst's theory of an incoordinate development of hypoblast and mesoblast, which he applies to both liver and kidney cysts, seems to be the same idea differently expressed. In re-

gard to the association with kidney cysts, Still in 1897 found this relationship in 35 recorded cases and added two more. Lejars, quoted by Hektoen, in 1889 found 17 cases out of a total of 63 instances of cystic kidney.

Case I.—Mrs. R., housewife, aged sixty years, died December 4, 1904, the clinical diagnosis being carcinoma of the stomach. I am indebted to Dr. Marie Olsen, who was occasionally consulted by this woman and attended her before death, for the clinical history, which, though incomplete, is quite interesting. The patient was a chronic invalid for many years. As a young woman she had multiple carbuncles of a very chronic type and was troubled with metrorrhagia. There was evidence of serious kidney lesions several years before death; pus, blood, albumin, and casts were found in the urine. The patient had consulted an oculist for rapidly failing vision; she was much troubled with vomiting; her complexion was "muddy," her breath exceedingly foul, and she was very cachectic.

She had complained for several years of distress in the region of the liver; some palpable swellings there had disappeared with some relief of local symptoms after massage (Traumatic rupture of cysts?). Swellings had also been palpated in the flanks. The patient believed herself to be suffering from cancer. A sister died some years ago, supposedly from cancer. She had presented very similar symptoms; Dr. Fenger had seen the case and had refused to operate. No autopsy was held in this case, although the patient had suggested that one should be held. The two sisters had at times spoken of their mother, who died in Germany, as having been a chronic invalid. The autopsy in the present case was held by Dr Bassoe, and the anatomic diagnosis was as follows: Cystic disease of the liver and both kidneys. Multiple suppurating cysts of the liver. Hypertrophy of the left ventricle of the heart. Edema and hypostatic congestion of the lungs. Diffuse bronchitis, chronic gastritis, uterine polypi, healed tuberculosis of the apex of the lung, localized fibrous pleuritis, corset constriction of the liver.

The autopsy record contains the following description of the liver:

"The liver is of abnormal shape, the anteroposterior diameter being the greatest. There is a constriction on both sides 10 cm. behind the anterior edge, at the points where the organ was in contact with the costal margins. The anteroposterior diameter of the right lobe is 28 cm., of the left lobe, 23 cm. The lateral diameter of the whole organ in front of the constriction is 19.5 cm. From above downward, the greatest dimension is 16 cm. near the posterior margin. The upper surface is uneven, due to the presence of a large number of cysts, which vary in diameter from 1 to 6 cm. They are scattered over the upper surface except in front of the constriction mentioned. Most of the cysts are translucent and on section are found to contain clear fluid. A few of the large cysts are opaque and dark red with reddish-black contents. Several dozen of the smaller cysts are yellowish-white and contain a whitish fluid of the appearance of thin pus. The inner surface is also the seat of a large number of cysts which, however, occupy a comparatively small part of the entire surface, as they are much smaller than those on the upper surface, the largest measuring 2.5 cm. in diameter. Between the cysts the surface is of a light brown color with distinct lobular markings.

In section the part behind the constriction mentioned is found to be honey-combed with cysts, the largest of which is located in the posterior part of the right lobe and measures 10 cm. in diameter. It has a thin fibrous lining everywhere, and is partly subdivided by incomplete partitions. Several small cysts project slightly into its interior. Many small cysts containing a yellowish fluid are seen on the cut surface and also several apparently solid yellowish areas 1 to 2 mm. in diameter. The liver tissue proper is of a brownish-gray color, with distinct lobular markings. The gall-bladder is of normal size and contains fluid bile. There are no concretions in the gall-bladder or the ducts. The diameter of the hepatic duct coming from the right lobe is 1 cm., that of the cystic duct also 1 cm., that of the beginning of the common duct 18 mm. No communication between the hepatic ducts and any cysts is noticed. The liver weighs 1,400 gms., after the evacuation of several large cysts."

The kidneys are described as follows:

"The right kidney unopened weighs 810 gms. and measures 23 x 9 x 8 cm. Its surface is everywhere composed of translucent, bluish-gray, opaque cysts varying from 1 mm. to 8 cm. in diameter. There is a distinct hilum into which cysts project. The cut surface is everywhere honeycombed with cysts varying in diameter from 1 mm. to 5 cm. There is no distinction between cortex and medulla. Only in a few places beneath the capsule a small amount of light-grayish kidney tissue can be recognized. The capsule is very adherent and cannot be removed without rupturing a large number of cysts. A pelvis is present into which large, dilated calices open. The pelvis itself is not dilated. The fluid within most of the cysts is mixed with blood.

"The left kidney weighs 700 gms. and measures 21 x 9 x 7.5 cm. Its surface is everywhere covered with cysts, the largest of which measures 7 cm. in diameter. The cut surface resembles that of the right kidney, being honeycombed with cysts. The pelvis is dilated and possesses distinct and dilated calices. There is little blood mixed with the cyst contents. The ureters are of normal size, as is the urinary bladder."

(To be Continued.)

A COMPARISON OF METHODS OF LAVAGE WITH THE SIPHON TUBE AND POLITZER BULBS.[1]

BY JOHN P. SAWYER, M.D.,
OF CLEVELAND, OHIO.

IN determining an ectasia or an atony of the stomach our criterion is the test of performance of muscular function as measured by residue of known food found after known periods of time. That this be accurate it is necessary that the amount obtained in the test be as nearly as possible the whole amount at the time present in the stomach. All agree that the recovery of this whole amount is difficult and often not accomplished, especially in the very group of patients in whom it is particularly desirable.

To meet this difficulty by the method of expression commonly used, various modifications have been proposed. Aspirators are numerous, and yet in the popular forms much gain in efficiency can hardly be claimed. Neither Fridlieb's, Boas' nor Straus' exerts more than an interrupted or slight aspiration. The application of a Politzer bag recommended by Ewald, arranged by Kuttner with a hard rubber connection piece, separable for convenience, is the most efficient simple form of aspiration.

The fact that the expression method leaves something to be desired even for the withdrawal of test meals is shown by Fleiner's recommendation, endorsed by Riegel, to have the patient, after expression in the sitting position, lie down for the purpose of obtaining a further quantity likely to be gained after all possible has been expressed by the atonic stomach in the upright body position. It needs but trial in a few cases to convince the investigator that a considerable amount can be withdrawn by the bulbs after all possible has been expressed in the sitting and reclining position.

As examples of the comparative efficiency of expression and aspiration of these bulbs I give a few figures of a trial made on the following plan. They can be multiplied indefinitely but are simply illustrative. In the first trial the patient, thoroughly used to expression and use of the tube, with a considerable motor insufficiency, four hours after the breakfast gave 95 c.c. by expression, and a further quantity of 40 c.c. was obtained by the bulbs. (Expression in the sitting and lying position.) An error of over 30 per cent. is possible by the expression method.

In the second example the patient used to expression and the bulbs, afforded 5 c.c. of thick mucus by the expression in sitting and lying position and 35 c.c. in addition was withdrawn by the bulbs. In this case but 12.5 per cent. of the recoverable stomach contents was obtained by the expression method, and this case also illustrates the advantage of the bulbs in the case of the tenacious mucus of the catarrhal process, in that much shorter tubes afford less opportunity for retarding the flow from the stomach by adhesion of the mucus to the walls of the tube.

The third example is that of a patient considerably used to the tube in whom 60 c.c. was obtained by expression in sitting and lying position, and the use of the bulbs with manipuation gave 20 c.c. additional. In this case 75 per cent. of the stomach contents was recovered by expression.

What is found in practice with the siphon expression in recovering food residue applies also to its use in lavage. In the ordinary sitting position and also in the horizontal position siphoning and expression permit in many cases considerable quantities of water to remain in spite of all reasonable effort. In upright positions the cardiac portion of the stomach often escapes the washing undertaken. Thorough cleansing of the stomach surface is accomplished, if at all, in considerable time and with fatigue to the patient. This thorough cleansing is often not obtained, especially when there is a catarrhal secretion of the membrane. The water goes into the stomach from the tube and back with little motion or current to perform the mixture necessary to establish the cleansing desired. These difficulties are overcome with ease for the patient, thoroughness in the result, speed and satisfaction to the physician or nurse, by using the bulbs for lavage as well as for aspiration of test meals, with manipulation of the stomach, shaking and mixing the solution used with the stomach contents, and later, upon the thoroughly cleansed mucosa.

I use the simple Politzer bulb with the glass connection fitting into bulb and tube. An empty bulb and two or three filled with solutions which are to be employed in succession as desired by the one giving the treatment, are provided. I find it most efficient to have the patient always in the reclining position, clothes thoroughly loosened. The food residue having been aspirated as completely as possible with an empty bulb, a bulbful of solution, medicated as desired, is introduced slowly into the stomach, and free, active manipulation of the anterior abdominal wall over the region of the stomach is used with sufficient energy, sometimes also shaking the posterior surface of the stomach, especially in conditions of atony or ectasia without ptosis. By this is produced a considerable movement of the liquid within the stomach useful for thorough cleansing and bringing the drug in close contact with the cleansed membrane. Then I allow the contents to be withdrawn in the aspirator which has been controlled by pressure with the hand till this time, and cleansing of the viscus can be accomplished more thoroughly, in less time, with less fatigue to the patient, than I can accomplish it by the use of the siphon tube. That the whole quantity used as a wash is withdrawn is seen by the filling of the bulb. The patient is freed from efforts at

[1] Read before the American Gastro-Enterological Association, New York, April 24 and 25, 1905.

expression, and lying as quietly relaxed as possible gains much in comfort.

With reference to the thoroughness I would call attention first to the recognized fact that frequently after the water is obtained clear in ordinary lavage there will sometimes be a marked rush of apparently pure food residue which has escaped the ordinary attempt at cleansing. This difficulty I do not find in practice with the procedure described.

As to the comfort of the patient the testimony of those in whom the two methods have been tried is strongly in favor of this method as easier and more cleanly; and they emphasize the freedom from straining and the annoying gagging or retching sometimes associated with expression.

As to the possible danger of injury, it is subject to the ordinary precautions which we would use in states of active inflammation of the membrane, in conditions of gastric ulcer, perigastritis and the like, which control our application of the siphon tube. Bits of membrane, blood, etc., are not more often found in washing by this method than by expression. My judgment on the basis of five years' routine use is that by the avoidance of straining by the patient the possibility of damage from this cause is lessened.

As to convenience and cleanliness for the operator, my own experience in this respect has been confirmed by many of my colleagues and assistants who using the procedure, express themselves as highly pleased with its convenience, speed and comfort.

I wish to draw especial attention to the advantage in lavage of having the patient reclining with loosened clothes, and then making use of free manipulation of the stomach wall to secure a more thorough cleansing and the more thorough application to the mucous membrane of suitable solution chosen for direct medication. In this fashion all the solutions used may be employed with a reasonable certainty that all portions of the stomach membrane are reached in the treatment and that all of the solutions injected are withdrawn.

MEDICAL PROGRESS.

PATHOLOGY AND BACTERIOLOGY.

Spontaneous Retrocession of Osteomalacia.—The course of this disease is considered to be progressive, only to be arrested in certain cases by ovariotomy. A case reported by P. Berger (*Comptes Rendus*, March 27, 1905), was that of a boy, who in 1895, after an osteotomy for the relief of bow-legs, began to develop marked signs of osteomalacia, of which the bow-legs had probably been an initial symptom. There was a progressive softening of the bones of the extremities, accompanied by loss of mobility, pain, incontinence of urine, which continued for three years, when, in 1898, there occurred a sudden arrest in the cause of the disease. The bones of the pelvis, neck, spine, and head, were not affected by softening. Since that time there has been a gradual improvement, a return of the bladder-function, and a recovery of the use of one arm. A comparison of radiographic records showed a recalcification of the latter. During the stage of progressive evolution of the disease, the excretion of lime salts in the urine was enormous, and during the stage of arrest, the amount, although diminished, was still large. At this time the X-rays revealed a vesical and a renal calculus, although there were no symptoms pointing to these complications.

Experimental Acid Dyscrasia.—An investigation of the relationhip between acidosis and natural resistance to infection was made by M. Charrin (*Comptes Rendus*, April 10, 1905). Three series of rabbits of the same weight and health were experimented upon. In the first, injections of sodium chloride were made intravenously; the second received injections of lactic acid, while the third were left alone. A little later all of the rabbits received the usual lethal doses of tuberculin. Those that had received the lactic-acid injections were the first to die. This result indicated to the author that the presence of too much acid in the blood diminishes the resisting power of the organism. Lactic acid is not the only acid that will do this. The author sees in the recent enthusiasm for the lactic-acid cure of certain diseases, as dyspepsia, gastro-enteritis, etc., with kefir, buttermilk and other foods containing lactic-acid, a possible element of danger.

Hyperplasia of the Chromophile Cells of the Hypophysic as the Cause of Acromegaly.—The apparent lack of similarity in the pituitary changes described in cases of acromegaly, the absence of evidences of acromegaly in instances of marked disease of the hypophysis from syphilitic and other chronic inflammations of the granulomatous type, the contradictory results following complete destruction or experimental removal of the gland, and finally, the occasional observation of cases of acromegaly in which the gland is of normal size and apparently not diseased, have inclined many investigators to discredit Marie's theory that disease of the hypophysis is to be regarded as the causative factor in acromegaly. It has been suggested that enlargement of the gland is secondary to enlargement of the sella turcica. D. D. Lewis (*Bull. Johns Hopk. Hos.*, May, 1905) after a careful histological study of the pituitary body in a case of acromegaly, is inclined to the view that the anatomical lesion present in the hypophysis is a hypertrophy and hyperplasia of the chromophile cells. In this view he is supported by the previous findings of Benda, who reported the histological changes in four cases of acromegaly and decided that there is an increase of the chromophile cells in the pituitary body, indicating an excessive activity of the gland. He also considers that mistakes in anatomic diagnosis account for the lack of uniformity in the descriptions of the lesions of the hypophysis associated with the disease. These statements are confirmed by those previously made by Le Count and Brooks, that many of the cases reported as sarcoma, angiosarcoma, lymphadenoma, etc., of the hypophysis are simply instances of hyperplasia or adenoma. The following pathologic conditions have been described in the hypophysis in those cases of acromegaly in which it has been enlarged and obviously diseased; *e.g.*, simple hypertrophy, twice; adenoma, seven times; sarcoma (variety not specified), five times; large-cell sarcoma, six times; cystic tumors, twice; hypertrophy and colloid degeneration; marked colloid degeneration and hemorrhage; sarcoma or glioma; spindle-cell sarcoma; cylindroma; round-cell sarcoma; glioma, adenoma with enlargement, one each. Further cases in which there have been found pathologic conditions of the hypophysis without any symptoms of the disease, are as follows: Cases of adenoma by Erdheim and Breitner; tumor (variety not specified), by Pon-

fick; simple hypertrophy by Packard; telangiectatic sarcoma by Cagnetto; sarcoma of the periosteum or dura of the sella turcica compressing the hypophysis and teratoma of the infundibulum by Benda; psammoma by Woollcombe; gumma by Beadles and Hektoen; tuberculosis by Beadles; and sarcoma by Hinsdale and, finally, a case by Bassoe in which the hypophysis weighed 5.9 gr. and another in which a small calcareous nodule was found in the gland, both without symptoms of acromegaly. Other theories mentioned by writers are (1) nervous theory; (2) theory of growth anomaly; (3) thymus theory; (4) genital theory and (5) thyroid theory. The author concludes that all these theories have met with serious objections and considers that there are many factors in lending support to the theory that acromegaly is caused by an excessive function of the cellular elements of the anterior lobe of the hypophysis.

OBSTETRICS AND GYNECOLOGY.

Technic of Operations for Uterine Fibroids.—J. R. GOFFE (*Am. Jour. Obstet.*, May, 1905) offers the following technic as satisfactory in operations for uterine fibroids. After opening the abdomen, while the tumor is *in situ*, the ovary and tube on one side are drawn up and the ovarian artery controlled by passing a ligature through the top of the broad ligament near the uterus. One end of this ligature is rethreaded and the broad ligament transfixed a second time near the tumor just above the uterine artery. A ligature having been placed near the horn of the uterus, the broad ligament is cut down to the point of transfixion, the tumor rotated, and the same method pursued on the other side. After delivery of the tumor through the wound, the lower angles of the incisions are connected by anterior and posterior oval incisions through the peritoneum covering the uterus. The flaps are dissected down, the one in front carrying the bladder and ureters into safety. One end of the original broad ligament ligature is passed inside of these flaps close to the cervix on each side and the uterine artery ligated. The tumor is then cut away on a level with the internal os, the canal disinfected with pure carbolic acid, and the flaps stitched over the stump and all the ligatures on either side. This method involves a minimum loss of blood, is easy and permits of rapid execution. Myomectomy, in the absence of definite contra-indications should always be preferred to hysterectomy. The vaginal route is to be preferred when the tumors are less than three inches in diameter. The elements of danger in operations for fibroid tumors are: (1) The wounding of the bladder, which may be carried high up by the tumor. (2) Wounding the ureter in ligating the uterine artery. The carrier should be passed downward and inward, parellel with the ureter, hugging the cervix. (3) Insufficient peritoneal flaps to cover the uterine wound in myomectomy. To allow for retraction of the tissues after shelling out the tumor, it is best to incise directly over its summit and perform any necessary trimming later. (4) Wounding the intestine in separating adhesions. Any necessary sacrifice of tissue must be at the expense of pathological mass rather than of the intestine.

Peripheral Paralyses of Pregnancy.—The peripheral paralyses of pregnancy may be divided into myopathic and neuritic. According to R. v. HOESSLIN (*Münch. Med. Woch.*, April 4, 1905), the paralysis of osteomalacia is the most important representative of the former group. The muscular changes here are not a result of the bone affection, but are probably caused by the same toxic agent. The chief symptoms are lassitude, tremor and muscular pains; later there is a tendency to the formation of contractures in the adductors of the thigh. The iliopsoas, quadriceps and the adductors of the thigh are paralyzed early, giving rise to the characteristic gait. The condition resembles very closely the juvenile form of progressive muscular atrophy, but the pseudo-hypertrophy is absent. A second form of myopathic paralysis is due to polymyositis, such as may occur under normal conditions as well as after severe puerperal sepsis. Neuritic paralyses are classed by the author as follows: (1) Traumatic neuritis puerperalis, caused by instruments, particularly the forceps, or by prolonged pressure of the head. There are a large number of cases, however, where the cause of the paralysis cannot be discovered. The nerves chiefly affected are the crural and the obturator. Severe pains often accompany the paralysis, which may last weeks or months, but usually has a good prognosis. (2) Neuritis puerperalis per contiguatem. Inflammatory processes in the pelvis will here extend downward and set up an inflammation in the nerves. This form occurs some time after the birth, and is accompanied by the signs of inflammation in the other tissues. (3) Neuritis puerperalis post infectiosa. It is a strange fact that this type of neuritis is more common after the milder forms of febrile puerperal affections than after actual sepsis or pyemia. The ulnar and median nerves are the ones chiefly involved and other localizations are extremely rare. The paralysis is typical, but in the majority of cases complete restitution sets in after several months. (4) Toxic neuritis gravidarum et puerperarum. The cause here is probably autointoxication, and in a very large percentage hyperemesis has been present or develops simultaneously. This type also prefers the median or ulnar nerves, but cases are on record where the facial, trigeminal or the optic nerve were paralyzed. In exceptionally severe cases there may be a generalized polyneuritis with symmetrical muscular atrophy of all the extremities. An important complication of this condition is Korsakow's psychosis. The prognosis depends upon the extent; in severe cases the mortality may be as high as 20 per cent. Interruption of pregnancy may seem indicated, but this is often without avail, since the toxins also seem to form during the puerperium. Operation should therefore be restricted to those cases where the life is actually in danger.

Care of Premature Infants.—There are very few cases of the survival of infants born before the twenty-seventh to the twenty-eighth week of pregnancy. The premature baby is an undeveloped baby, the lungs contain little alveolar structure and are prone to congestion; the pulse and respiration are irregular from lack of nervous control and development. The stomach capacity ranges from 5 c.c. to 30 c.c., digestive functions are feeble, that for sugar being best developed while the amylolytic function is practically non-existent. The heat regulating centers are poorly developed, consequently extremes of temperature are dangerous. On account of the greater heat loss premature infants require one-fifth to one-fourth more calories per kilo than do normal infants, but, in spite of greater need for food, much to their disadvantage they are less able to take and digest it. In regard to the care of premature infants J. L. MORSE (*Am. Jour. Obstet.*, May, 1905) states that two objects are to be attained: To keep the baby alive, and to develop its organism. The infant should be protected from noises, bright lights, and unnecessary handling. For the maintenance of animal heat incubators and substitutes for incubators are used. Most incubators may be made to maintain a constant temperature, but none of them provide sufficient pure, fresh,

warm air. The best substitute is a crib basket, padded with cotton. The top should be covered with a blanket which reaches just below the baby's neck. The desirable temperature (90° to 95° F.) may be maintained by hot water bags or bottles, the temperature being taken from a thermometer wrapped in the baby's clothing. The temperature of the room should be 80° to 85° F. The baby should be oiled every three days, but not washed, and wrapped in a quilted gown with a hood. Absorbent cotton makes a satisfactory substitute for a diaper. The best food for premature babies is breast milk, diluted at first with one to three parts of water. Modified milk with low ingredient percentages is the best substitute for breast milk—5 c.c. should be given at first at 1½ hour intervals, the amount of milk and the intervals being gradually increased. When the infant is too feeble to take food from a nipple it may be fed with the "Breck Feeder," or a medicine dropper. When stimulation is indicated one or two drops of brandy, strychnine (1-1,000 gr.) and oxygen may be useful. Babies under two pounds usually die; the prognosis is very fair when over four pounds. A slight elevation of temperature is to be expected when the infants are doing well; those doing badly usually run a subnormal temperature. Sudden death may occur without apparent cause, hence it is never safe to consider premature infants out of danger until they are thriving under normal conditions.

THERAPEUTICS.

Iodide of Silver in Urethritis.—Considerable interest attaches to a proposal by E. H. Siter and A. A. Uhle (*Univ. Penn. Med. Bull.*, May, 1905), to employ this in preference to the other better known salts of silver. As it is not soluble, it becomes necessary to suspend it, and this was found to be best accomplished by mucilage of quince seed. This salt is not *proprietary*, and the exact strength can be controlled better than nitrate of silver. It does not stain, and is less irritating, therefore stronger solutions can be used. The writers claim that it reduces the acute stage to a minimum and relieves symptoms very quickly. They have used it in over a hundred cases, several typical ones being reported, and its effects were particularly good in dispensary patients who cannot be treated under ideal circumstances. The drug is given in from five to ten per cent. injections, three to four times daily. It was particularly noted that the ardor urinæ subsided within the first day and the discharge disappeared well within a week. In cystitis of prostatic origin or after prostatectomy it also yielded good results.

Treatment of Basedow's Disease.—That the antithyroidin of Möbius seems to have acquired a lasting place in the treatment of exophthalmic goiter, is evident from two articles contained in the *Münch. Med. Woch.*, May 2, 1905. Glomer gave the serum internally (0.5 c.c.) three times daily, to a patient suffering from general paresis, complicated by Basedow's disease. The pulse improved at once and became slower, the goiter and the exophthalmos were less marked after eleven days, and the tremor and Graefe's sign disappeared almost completely. As soon as the treatment was stopped the symptoms reappeared. R. Durig recommends much larger doses (up to 150-210 drops daily), even though slight after-effects (headache, apathy) may appear. The rectal application is indicated where the serum is not well tolerated by mouth, but somewhat larger doses are then necessary.

Graves' Disease and Parathyroid Therapy.—James J. Walsh (*Am. Med.*, May 20, 1905) reports four cases of Graves' disease treated with desiccated parathyroids on the principle suggested by Gley, of Paris; Munk, of Berlin, and confirmed by MacCallum, of Baltimore, that it is the absence of the parathyroid glands in the neck which produce the symptoms of Graves' disease. In two mild cases the remedy seemed to produce a good effect. Walsh concedes suggestion plays a large rôle in the relief, and in one case seemed to cause an exacerbation of In two severer cases the remedy failed utterly to give relief, and in one case seemed to cause an exacerbation of the symptoms somewhat as if thyroid extract were being given. It is not absolutely certain that the parathyroid material was entirely free from all admixture with thyroid substance, though it was very carefully prepared for these cases.

Tolerance to Nitroglycerin.—According to D. D. Stewart (*Journal A. M. A.*, May 27), an excessive tolerance to nitroglycerin can be readily acquired if care is not taken to avoid a too rapid increase of the dose, hence the drug, though intelligently employed, is often of little service. He refers to earlier articles of his on the subject, and especially to a case beforementioned in *Journal A. M. A.*, in which 50 minims of a 10 per cent. solution were taken daily without any very marked effects. The best rule for giving the drug for its effects on blood pressure is, in his opinion, to administer it four times a day in dose just sufficient to produce the slightest feeling of fulness in the head or to slightly quicken the pulse. If more than this is given, an undesirable tolerance is likely to be established.

PRESCRIPTION HINTS.

Loss of Appetite.—Dr. H. C. Wood recommends for failure of appetite, weak digestion and the general debility of warm weather the following stomachic:

℞ Acidi nitrohydrochlorici ..... ℥ii
Aquae ..... ℥i½
Strychniæ sulph. ..... gr.i
Misse et adde
Tincturæ cardamomi comp... } aa, q.s. ℥vi
Tincturæ gentian. comp..... }
M. Sig. Dessertspoonful after meals in water.

Pruritus Ani.—

℞ Hydrargyri chloridi corrosivi ..... gr.½
Ammonii chloridi ..... gr.iii
Acidi carbolici ..... ℥i
Glycerini ..... ℥ii
Aquæ rosæ ..... ℥v
M. Sig. Apply night and morning.

Amenorrhea.—In women suffering from amenorrhea due to deprivation and depressing hygienic surrounding, the late Dr. Goodell, of Philadelphia, placed great reliance in the "Mixture of the Four Chlorides."

℞ Hydrargyri chloridi corrosivi..... gr.i
Liquoris arsenic chloridi ..... gtt.xlviii
Tincturi ferri chloridi..... } aa ℥iv
Acidi hydrochloridi diluti ..... }
Syrupi zingiberis ..... q.s. ad ℥vi
M. Sig. Dessertspoonful in water after meals.

For Prickly Heat.—

℞ Zinci carbonati precip. ..... ℥iv
Zinci oxidi ..... ℥ii
Glycerini ..... ℥ii
Aquæ rosæ ..... ℥viii
M. Sig. Apply locally.

For Dermatitis Venenata from Poison-Ivy.—

℞ Sodii hyposulphitis ..... ℥i
Glycerini ..... ℥i½
Aquæ ..... q.s. ad ℥viii
M. Sig. Keep constantly applied.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 29, 1905.

REAPPEARANCE OF YELLOW FEVER.

There is a peculiar irony in the fact that while our sanitary authorities were so greatly exercised over a possible mote in Havana they should have been so unconscious of the beam in New Orleans.

In 1493 when Columbus landed in the island of Hispaniola he lost the greater part of his crew within a year from a disease now identified as yellow fever. From that time on, repeated and severe epidemics have originated in the West Indies, and spread with somewhat modified virulence to Central and South America, occasionally reaching the United States. The most serious epidemic which this country ever experienced was that of 1878-79, when the disease assumed epidemic proportions as far north as Tennessee.

The ignorance which prevailed at that time in regard to the etiology of the disease interfered materially with the effectiveness of quarantine. The most rigorous isolation of cases and elaborate precautions as to the disinfection of "fomites" proved strangely unavailing. Many and various theories were advanced to explain the curious statistics relating to the spread of the disease, the incongruities of which were too marked to escape notice. For instance, cases occurring among refugees in Cincinnati, Ohio, showed no tendency whatever to spread.

For years persistent efforts were directed toward discovering the specific organism, and a number of investigators, Freiere and Saranelli among others, claimed success. It was Dr. Finlay, of Havana, who in 1881 suggested that the infection might be propagated by the mosquito, but this suggestion was not worked out until nearly twenty years later, when Drs. Reed, Carroll, Agramonte and Lazear convened as a Board of Medical Officers for the purpose of studying the acute infectious diseases of the Island of Cuba. It is to the tireless patience, the devoted self-sacrifice and the inspired intelligence with which they pursued their task that the world owes its present knowledge of the etiology of yellow fever, and consequently of the means best calculated to check its ravages. They demonstrated conclusively that a genus of mosquito, the *Stegomyia fasciata*, acts as an intermediary host in the propagation of the infection. To be sure, the identity of the specific organism is still a matter of dispute, but whatever it is, the mosquito is an essential factor in its life history. Consequently, the investigations which have proved of practical value are those dealing with the *Stegomyia fasciata*.

The *Stegomyia fasciata* is essentially a house mosquito, and is seldom conveyed aerially more than 100 yards unless by strong currents of wind. It breeds in cisterns, water jars and pools. It will not feed in strong sunlight nor in the dark. It will live for 154 days or longer unless deprived of water, when it succumbs within five or six days. The distribution is general, from 36° N. to 35° S. latitude on the eastern coast of America. On the western coast it is present at Panama and Guayaquil, and probably from the latter place to Acapulco. In the United States it is found all along the coast and the low plains of all the Southern States except Maryland.

In view of these facts the prophylaxis is obvious. Its aims are twofold, namely, to destroy the *Stegomyia* and its breeding places, and to prevent those mosquitoes which do exist from becoming infected. The screening of all established or suspected cases, the abolition of open water receptacles and the draining of pools are measures which have proved effective. These should be supplemented by proper quarantine regulations. Even in the light of later discoveries, de-

tention and disinfection are still useful, not, as formerly believed, for the destruction of "germs," but in order to dispose of any infected mosquitoes which may have been transported, and to allow the elapsing of the incubation period in the case of persons who have possibly been exposed to infection. Since baggage, freight and mail matter can be a source of danger only when harboring mosquitoes, and since a period of five or six days after the packing of such parcels gives assurance that they contain no living *Stegomyia,* such matter is easily dealt with. Vessels can be considered "infected" only in the sense that they may act as a medium for conveyance of infected *Stegomyia,* and this danger is best removed by fumigation with sulphur, the insects being exterminated at the end of an hour and a half by this process.

As for cases developing during the voyage or after landing, they bring little danger to communities outside the domain of the *Stegomyia fasciata.* Within that region, however, the detention—always under screen—of suspicious cases is an item of first importance.

There is no doubt that the mosquito theory has been accepted by the medical profession of New Orleans, but it was quite another matter to arouse public sentiment to a degree that would insure its practical adoption. That the possession of this knowledge, however, creates a certain confidence among the public at large is evident by the way in which the latest outbreak is met. A slight tendency to panic, experienced in New Orleans on hearing of the visitation, promptly subsided, and there has been no attempt at general exodus such as previous epidemics have occasioned. Business progresses as usual and the authorities are dealing promptly and energetically with the situation. The continued spread of the disease thus far is doubtless due to the lack of intelligence among the inhabitants of the quarter where it has broken out. Such ignorance always constitutes a formidable obstacle in combating any infectious disease, but civilization is bound to conquer in the end, and there is every reason to believe that the scourge which threatens New Orleans will result in another notable triumph of science.

A SUCCESSFUL MUNICIPAL SANITARIAN.

A recent number of the Bulletin of the Health Department of Chicago contains, besides the notes on the state of Chicago's health, the farewell of the Commissioner, Dr. Arthur R. Reynolds, who has, for the last twelve years, so successfully managed the great western city's sanitary affairs. There is no one who is in a position to know the present state of Chicago's health and who has followed the course of sanitary affairs in that city during the last decade, who will not be ready to acknowledge how much Dr. Reynolds has accomplished for Chicago's health. We pointed out, over a month ago, the differences between Chicago and Philadelphia in the matter of the death-rate from typhoid fever. When Dr. Reynolds began his work in Chicago the city had a "bad eminence" in the matter of typhoid that made it Philadelphia's greatest rival Philadelphia's mortality from typhoid fever has continued practically unabated; that of Chicago has gradually become less and less, until, during certain weeks of the past spring, when typhoid fever is so often likely to be prevalent, no cases of the disease at all were to be found in this large city. Not all of this improvement is due to Dr. Reynolds; but undoubtedly much of the inspiration that forced politicians into the recognition of the necessity for sanitary improvements of various kinds must be attributed to him.

His methods deserve study by all who have the health of large cities in trust. His main idea was publicity for the state of the city's health and the causes of disease raging at any particular moment, and through this a crusade of education that would gradually produce an enlightened public opinion in matters of municipal sanitation. His principal merit has been that he has succeeded in doing this not only without producing enmity, but actually in such a way as to band together many hitherto discordant elements in Chicago's municipal life. Above all, Dr. Reynolds has known how to secure the cooperation of the medical profession of the city and, while working with them, to lead them to more definitely practical ideas of sanitary science and hygiene and secure their coöperation in the education of the people. The Bulletins of the Health Department of the city of Chicago have come to be recognized as important documents for the spread of practical ideas in sanitary science. While the announcement of deaths usually made in such bulletins might very well seem to preclude the possibility of their becoming interesting popular reading, Dr. Reynolds has succeeded in making them valuable auxiliary documents in his educational campaign so that they have been

eagerly taken up by women's clubs and kindred organizations and widely distributed until, as Dr. Reynolds with pardonable pride proclaimed before the Sociology Club of Chicago University, two years ago, "the average Chicago citizen is more intelligent in sanitary matters than his brethren of any other city in the country, and consequently the average duration of life in Chicago has more than doubled in a single generation."

Certain features of Dr. Reynold's work seem deserving of special mention. To him more than to any other in this country is due the recent calling of public attention to the increase in the death-rate from pneumonia and the consequent endeavor to learn more about the disease so as, if possible, to prevent its widespread ravages. He emphasized the fact that pneumonia had taken the place of tuberculosis as "the captain of the men of death," so often in the Bulletin of Chicago Health Department, that sanitarians generally found themselves compelled by popular interest to take up the investigation of this important subject. It seems not unlikely that as the result of this movement we shall learn more about pneumonia in the next few years than has been learned during nearly the whole of the preceding century. It is interesting to note that while he has been insisting so much on the place that pneumonia has come to occupy in the death-rate, tuberculosis has not been neglected, and there has been, during the last ten years, a reduction of 14 per cent. in the mortality from that disease.

Perhaps the most valuable work of the late Commisioner of Health of Chicago has been done with regard to smallpox and vaccination. Just after Dr. Reynolds assumed charge of the city's health, a terrible and costly epidemic of smallpox broke out in Chicago, and seemed to demonstrate that the protection afforded by vaccination was illusory. The Health Commissioner proceeded at once to the insistence upon proper vaccination of all the inhabitants of the city. Chicago, with its heterogeneous population exposed to frequent importation of the contagion, needed to be completely revaccinated. This was accomplished in spite of discouragements of many kinds, and even direct opposition from many quarters. As a consequence, the bulletins of the Health Department of Chicago have been in a position to demonstrate in recent years with a definiteness unknown anywhere else in the world outside of the German Empire the absolute protective value of vaccination. During the past three years the collection of vital statistics and investigation of individual cases has shown over and over again that the persons attacked by smallpox were those who had not been vaccinated or in whom vaccination had been performed so many years before that its protective and immunizing value had been exhausted. Especially was it made clear that in families where all had been vaccinated, excepting the children under the school age, these were the only ones to take the disease after exposure, and they unfortunately constituted a large proportion of the fatal cases.

There is no doubt that Commissioner Reynolds has fulfilled his duty with eminent success. Chicago's death-rate, which, when he began his work, was one of the highest among the large cities of the country, is now among the lowest, if not the lowest, of them all. The mortality has been reduced over 25 per cent., while there are other large cities in which there has been no reduction in mortality during the same period, and none have had a reduction equal to Chicago's. Even above what Dr. Reynolds has done for Chicago, however, has been and will be the example of his work for the heads of departments of public health in other large cities throughout this country. It is not from Chicago perhaps that such an example would have been ordinarily expected. That it has been given there reflects all the more credit on the man who, in spite of difficulties and political friction and municipal disadvantages in a rapidly growing city, succeeded in accomplishing so much to make life more livable, health more enduring and the generation longer in the city by the lakes.

ECHOES AND NEWS.

NEW YORK.

Plan Adopted to Ventilate Subway.—Huge fans which will carry the foul air out of the Subway, allowing a fresh volume to flow in, and openings in the roof of the tunnel are the main features of the plan which is to be put in operation at once. Hundreds of small rotary fans, Mr. Hedley explains, have been put in at all the stations.

Leper to be Deported.—Said Ben Ali, an Algerian, who arrived here on July 11, in the steerage of the steamship Philadelphia, has been refused admittance by the immigration authorities and will be deported. He was found to be suffering from a disease which, after examination by several surgeons, was pronounced to be leprosy. The Algerian has been kept in strict isolation since his arrival here.

New York Hospital to be Enlarged.—Plans have been filed with Building Superintendent Hopper for the enlargement of the operating amphitheater on the top

of the east wing of the New York Hospital, in West Fifteenth Street, into a two-story edifice of faced brick, with fire-proof galleries and floors and walls of marble and tile. It is to have an ornamental skylight and cabinets for the storage of surgical instruments. The improvements are to cost $20,000, according to the estimate of the architects, Trowbridge & Livingston.

Increase in Death Rate.—The effects of last week's hot wave are strikingly set forth in the figures issued by the Bureau of Vital Statistics for the week ending last Saturday at noon. The total number of deaths during the week was 2,119, as against a total of 1,726 for the corresponding week in 1904. Of deaths due directly to the heat, there were 151, as against only eight during the same week a year ago. Intestinal troubles, more prevalent during a heated term than any other, last week caused no less than 685 deaths, an increase of 132 over the corresponding week last year. The same deadly showing is furnished by the record of deaths from heart disease. Last week there were 109 fatal cases of heart trouble, while the week before there were but 88. For the corresponding week of 1904, the record showed 70. In the matter of cerebrospinal meningitis the hot spell seemed to be beneficial, the number of deaths from that disease being but 22 during the entire week ending last Saturday. The percentage of deaths was 28 in 1,000, as against but 23 in 1,000 during the same week in 1904.

Ignorant Mothers Taught.—In the wake of the torrid weather of the past week, there have come to the knowledge of the doctors and nurses of the Sick Children's Mission of the Children's Aid Society scores of instances of sickness and deprivation. The timely calls of the physicians and nurses of the society since their work began in June has resulted in the saving of the lives of many young babies, who were discovered to be suffering from ailments incident to the season and from the effects of improper diet. The visitors find the greatest ignorance on the part of the mothers in regard to the feeding and care of the young children. In numerous instances the doctors have found that the mothers permit their children to eat freely of cucumbers and decayed fruit. The Sick Children's Mission is putting forth every effort to teach these mothers in the so-called foreign quarters a better way, while giving the necessary medical treatment and nourishing food to the helpless babies. To meet the demands of this work, funds are needed. Checks may be made to the order of V. B. Hepburn, treasurer, and sent to No. 105 East Twenty-second Street.

City's Poor Ambulance Service.—A paper by Nathan Bijur was read at Portland, Ore., before the Thirty-second National Conference of Charities and Corrections on New York's inefficient ambulance service. He advocates the appointment by the Mayor of a commission to investigate the subject, and proposes as a temporary solution of the problem the establishment of a central ambulance bureau, to be connected with the Police Department, which can receive and record all calls, and, in harmonious working with the hospitals, provide for the promptest service possible under the circumstances. Mr. Bijur holds up New York's Fire Department as a means of comparison to show the marked deficiency in the city's really serious effort to render first aid. He called attention to the irregular disposition of the hospitals over the city, there being an entire absence of any geographical plan or method in their location. The expense involved in the establishment and maintenance of an ambulance service is no excuse for its absence or incompleteness. The cost of an ambulance, with two horses (for relays), harness and equipment, appears to be between $1,000 and $1,200. The cost of annual maintenance is about $1,000, exclusive of rental of station, and assuming the services of the surgeon to be gratuitous, or at least to be included in the general expenses of the hospital or similar institution to which the ambulance is attached.

PHILADELPHIA.

License for Recent Graduates.—As a result of the examinations held less than a month ago, 51 of the applicants were given licenses to practise medicine. Of the 36 homeopathic graduates who took the examination every one passed, while 4 of the 19 eclectics failed.

Honored by Edinburgh University.—While attending the quater-centenary celebration of the Royal College of Surgeons, at Edinburgh, Dr. W. W. Keen, of Philadelphia, and Professor of Surgery at the Jefferson Medical College, received the honorary degree of Doctor of Laws at a special graduation ceremony of the Edinburgh University. In an address he paid a glowing tribute to the Edinburgh University, which, he said, "the Transatlantic graduates regard as their academic Jerusalem."

Consumptives Barred from Attending Church.—Rumors are current that the council at White Haven, Pa., proposes to pass an ordinance which is to prevent patients suffering from tuberculosis from attending church in that town. The ordinance, it seems, is a blow aimed at the patients of the Free Hospital for Consumptives. Dr. Lawrence Flick, president of the institution, believes that such action would be the height of folly, and, in his estimation, could not be enforced, since it is a restriction of personal rights, which is unconstitutional. Dr. Flick believes there are tuberculous patients in White Haven who are not inmates of the sanatorium, and who are dangerous because they do not comply with the rules laid down for treatment in the institution.

Heat Increases the Mortality.—As a result of the prolonged hot weather, the deaths in the city numbered 608 last week, whereas during the previous week but 548 died. The weather spent its greatest effect upon children and upon the aged; of the 608 deaths, 233 were children. Insolation was responsible for 19 deaths. The greatest surprise is the evident increase in the death-rate of typhoid fever. During the week just ended 108 new cases were reported and 18 deaths occurred, whereas during the proceding week but 12 patients died. Of the cases of contagious diseases reported 21 were diphtheria and 13 scarlet fever. As has already been pointed out in this column several times, the greatest number of typhoid cases are from wards which receive water directly from the Delaware River.

CHICAGO.

Rabies.—One death from this disease is reported to have occurred at the Presbyterian Hospital on July 8. The victim was bitten by a pet dog at his home in Russell, Ky., and did not receive medical attention until too late.

Appointment of Dr. Reynolds.—Dr. Arthur R. Reynolds, until the Dunne administration Commissioner of Health of Chicago, will leave this city on August 1 for French Lick Springs, Ind., where he has been appointed resident physician and director of Thomas Taggart's Hotel.

Departure of Dr. Senn for Northern Latitudes.—Dr. Nicholas Senn, of Rush Medical College, is to have a taste of Arctic travel, and, it is said, a

share in the Peary expedition, although he will not attempt to reach the Pole. He was a passenger on the Arctic steamer Erik, which sailed recently from Cape Sabine, North Labrador, which was going with coal and supplies for Peary. The Erik will meet the Roosevelt at North Star Bay, and then return south early in September.

Lawn Fete Aids the Hospital.—The lawn fête given by the auxiliary association of the St. Francis Hospital at Evanston, to aid the charity patients, which closed July 20, was a financial success. All the booths were patronized liberally and the attendance was unusually large. The receipts exceeded $1,000, which was the amount the committee had determined to secure. The money will be used to aid patients of the hospital who are unable to support themselves until some permanent means can be found for providing for them. The hospital has been in existence five years, and although under strictly Catholic management, it is conducted without regard to the creed of the patients.

Public Health Matters.—According to the weekly bulletin of the Chicago Health Department, for the week ending July 22, 627 was the total number of deaths from all causes, an excess of 180 over the previous week—188, or 30 per cent. of the total, were of infants under one year of age, and 57, or 18 per cent. of the total, were of children between one and five years of age. These age periods were the greatest sufferers from the effects of the heat, and next to them was the other extreme of life—those over sixty years, which show an increase of more than 46 per cent. Directly and indirectly due also to the heat of the early part of the week are the 22 deaths from sunstroke; the 78 more deaths from acute intestinal diseases; 27 more from heart diseases; 24 more from consumption, and the increase in deaths from pneumonia. In this latter case the increase is of terminal pneumonia, or pneumonia terminating some form of chronic disease. Of the 150 deaths returned as due to intestinal diseases—an increase of 78 over the previous week—122, or 81.3 per cent. were among infants under one year old. During the week five deaths were reported as caused by tetanus, two of which were due to Fourth-of-July accidents. Ten deaths from tetanus have been reported since July 1, of which five were due to Fourth-of-July accidents.

GENERAL.

A New Anesthetic.—Two German scientists announce in the *Deutsche medicinische Wochenschrift* the discovery of a new anesthetic having all the virtues of cocaine without its secondary ill-effects. The new substance is called "Allypine." It deadens pain by local application and does not contain poison.

Dental Congress at Portland Fair.—The Lewis and Clark Dental Congress began a four days' session July 18, with more than 300 members of the profession in attendance. Eight Western States were largely represented, fifteen States in all sending delegates. There were also dentists present from Singapore, Honolulu, Canada, New Zealand, and Alaska. The officers of the Congress are Dr. Norris R. Cox, President; Dr. Arthur W. Chance, Secretary and Treasurer.

Honored at Edinburgh.—At a special graduation ceremony at Edinburgh University on July 22, the honorary degree of doctor of laws was conferred on Ambassador Paul Cambon, Prof. William Stewart Halsted, surgeon-in-chief of the Johns Hopkins Hospital, and professor of surgery in the Johns Hopkins University of Baltimore; Prof. I. H. Cameron, of Toronto; Prof. F. J. Shepherd, of Montreal, and Prof. William Williams Keen, professor of surgery, Jefferson Medical College, all of whom were attending the celebration of the quater-centenary of the Royal College of Surgeons.

For Mosquitoes, Maryland.—Thoroughgoing investigation of the mosquito, its haunts and its habits, which has been in progress for some time under the direction of the scientific department of the Johns Hopkins University, has resulted in the discovery officially announced by the Hopkins authorities, that Maryland has the largest mosquitoes to be found in this country. No exception is made of New Jersey. The Maryland mosquito is positively pre-eminent for size and ferocity. The investigation also shows that Maryland breeds specimens of almost every kind of mosquito, including the malaria-breeding kind.

New Hospital for East Boston.—An emergency hospital is now assured for East Boston. Mayor Collins affixed his signature July 24 to the order which passed both branches of the city council unanimously, providing for an emergency hospital in that section of the city. The order calls for an appropriation of $30,000, and to this amount is added about $11,000, the bequest of the late Ann E. Taggard, who stipulated in her will that the money should be used for hospital purposes in the East Boston district. The proposed hospital is to be built under the supervision of the trustees of the City Hospital.

Gen. Wood's Illness.—Gen. Leonard Wood, who was recently operated upon at St. Margaret's Hospital, Boston, is progressing so well that his family now expect him to be at his old home in Pocassett in a few days in comparatively good health, and ready for a trip back to his post in the Philippines. The exact cause of Gen. Wood's trouble was made public for the first time. It is exostosis of the head; an abnormal growth of bone or bony tumor upon the skull. The cause was a blow upon the crown of the head, sustained about a year ago. The operation was performed on July 5 and was entirely successful.

The New Jersey Village for Epileptics.—The seventh annual report of the New Jersey State Village for Epileptics just issued, reports that the general health has been good and the inmates seem to be happy and contented. Epileptic seizures are reported by cases, giving the number in so many months, and a large decrease is shown in the year ending November 1, 1904, over the number of the preceding year, the monthly average being, for males and females, respectively, 307 and 245, as against 366 for each sex the previous year, this notwithstanding the increased number of patients. There are 93 inmates, six having been discharged and three having died during the year. New buildings are progressing, appropriations having been made by the last legislature, and the capacity of the village will soon be considerably increased. It was expected that by July 1, there would be room for 300 patients. Plans for original investigation of the malady and for more complete scientific treatment, are pending

All Should Live 100 Years.—Sir James C. Browne, the author of various works on mental and nervous diseases, in an address to the Public Health Congress in London, declared it was a good working hypothesis to regard the natural life of man as one

hundred years. He did not agree with Prof. Osler and others that the world's effective, vitalizing work was done between the ages of twenty-five and forty years. Much of the world's best work, he said, had been done by men over forty years of age. If the world were deprived of their work it would go back to the twilight of ages ago. Every child should be brought up impressed with the obligation of living to a hundred years, and should be taught to avoid irregularities in living which tend to prevent the attainment of this ambition. While it was certain that a century of health and vigor could be attained, it could only be reached by faithful obedience to the laws of health and simplicity and tranquility in living.

St. Louis Skin and Cancer Hospital.—On July 1 the St. Louis Skin and Cancer Hospital opened its doors for the reception of patients. This institution, situated on the southeast corner of Jefferson and Charles streets, consists of a completely equipped hospital of forty beds, and an outpatient or dispensary service. As the title indicates, only skin and cancerous diseases will be treated. The institution is founded upon the idea of research in cancer and allied types of malignant diseases. A pathologist, who will devote all of his time to the needs of the hospital, has been appointed, and he will conduct such scientific investigations as the opportunities of the hospital and clinic will permit. The medical staff of the institution will also, especially, direct their efforts to scientific endeavor. A training school for nurses, partaking of the character of a postgraduate school, has been established in connection with the hospital. Daily clinics for outpatients will be held. The institution is to be free of charge to all patients enjoying its benefits. Inoperable and incurable cancer cases, as well as the more hopeful ones, will be admitted to the hospital; the Society expects, in the near future, to have a home, situated somewhere in the suburbs of the city, for the former cases. The following medical staff has been appointed: Dr. G. Baumgarten, Dr. N. B. Carson, Dr. J. R. Clemens, Dr. M. F. Engman, Dr. A. E. Ewing, Dr. E. C. Burnett, Dr. W. E. Fischel, Dr. Frank R. Fry, Dr. George Gellhorn, Dr. John Green, Dr. John B. Keber, Dr. F. J. Lutz, Dr. Guthrie McConnell, Dr. H. G. Mudd, Dr. Greenfield Sluder, Dr. J. B. Shapleigh, Dr. Ellsworth Smith, Jr., Dr. Justin Steer, and Dr. Fred Taussig.

Boston's New Affliction.—About five years ago Malden, Medford and Everett were invaded by the brown-tailed moth; this insect, much more active and vigorous than its rival the gypsy moth, has spread in a remarkable fashion so that now very few of Boston's suburbs are free from its ravages. Along with the reports that many fine trees had been killed and the beauty of avenues destroyed, have come from time to time, chiefly from among those engaged in fighting this pest and the inhabiatnts in the affected districts, complaints of a very troublesome and painful rash, occurring usually on the exposed parts of the body at that time of the year when the moths were in the caterpillar stage. At first no cause could be assigned for this trouble, but now it is definitely known that it is these caterpillars who are to blame. Until recently very few of such cases have reached the city dispensaries and it was not until this year that many Boston physicians have come actively into contact with this condition. This season, however, the army of beautiful white moths invaded Boston itself, caterpillars have abounded on roads, sidewalks and trees, so that almost every one in the town has had an opportunity to learn from personal experience what the brown-tailed moth rash is like. The caterpillars hatch out in the early spring and again late in August; they are plentifully provided with stiff, many-pronged hairs which are apparently but loosely attached and, set free by the slightest force, are thrown into the air. These fall on the arms, face and neck of unfortunate individuals and also on wash hung out to dry, so that the rash may be found on any part of the body. The rash itself is usually localized in the form of many discrete papules, intensely painful and itching, lasting from one to two weeks. Most cases require no treatment beyond the simplest of home remedies, but some are reported from Newton where the eruption was general, the eyes closed, and hospital treatment necessary. The complaint is a very real one and, although the entire subject has been the source of many jokes, to the one afflicted it is no laughing matter.

OBITUARY.

Dr. Curtis Harvey Bill, of Bridgeport, Conn, aged seventy years, a leading physician of Fairfield county, died July 24, from the effects of an abdominal operation performed the preceding Tuesday at St. Luke's Hospital, New York. He was a native of Tennessee, but had resided in Connecticut since the Civil War, in which he served as a surgeon.

Dr. H. J. Schiff, of 117 East Seventy-ninth Street, New York, dropped dead on the steamboat pier at Alexandria Bay on July 24. He was on his way to Ogdensburg, to attend the State convention of the Knights of Pythias.

Dr. Joseph Burr Bennett, who was one of the oldest homeopathic physicians in Brooklyn, died on Sunday at his home, 108 Columbia Heights. He was born at Saugatuck, Conn., eighty-nine years ago, and came of Colonial stock. He began practising as a physician in Brooklyn sixty years ago. For the past twenty years he had devoted himself to the care of his property. Dr. Bennett leaves six children.

Dr. Anna Frances Donoghue died on the morning of July 20, at her apartments in the Grenoble Hotel. She had suffered from heart disease for some time, and had predicted that death would come, as it did, while she slept. Dr. Donoghue was born in Newburgh, N. Y., in 1873. She was graduated from the Albany Normal School in 1888, and shortly afterward entered the New York Medical College for Women, from which she was graduated in 1894. Dr. Donoghue was a member of the Eclectic, Rainy Day and Minerva clubs. She is survived by two brothers, Joe Donoghue, and James Donoghue, a detective of the West Forty-seventh Street police station.

Dr. Benjamin Edge died at his home in Jersey City, July 25. He was born May 17, 1851, and was sent to London, where he received his early education at Clapham College. Returning, upon the death of his father, to this country, he completed his medical studies at Bellevue Hospital, receiving his degree in 1878. In 1884 Governor Abbett appointed him a member of the State Council of Charities and Corrections. In 1901 Governor Voorhees made him a member of the State Reformatory Commission. His grandfather, Isaac Edge, came from England, and built the fourth house erected in Jersey City.

CORRESPONDENCE.

"PULSE IN VERBAL RHYTHM."

Editor of the MEDICAL NEWS:

DEAR SIR: In the current number of *Poet Lore* there is an article on "Pulse in Verbal Rhythm," which contains a suggestion calculated to be of great interest to physicians.

The article is by Mme. Mary Hallock, the pianist, and deals with the clock time rates which can uphold the feeling and not distort the form of poetry. It is demonstrated that the scope of speed covered is coincident with that of the pulse considered in its cycle of general and individual variation.

The physiologieal explanation suggested is that the mechanical jutting out of the arterial walls with every heart-beat jostles the network of nerves which surround them to urging a compensating action. This is the more readily to be believed when one keeps in mind the fact that these time rates are palpably not necessary, but are born of habit bred from unremitting suggestion. The mechanical energy refered to is that which grows out of the check given to the arterial flow by the capillary system.

All physiologists know the stimulus is no slight one. The same writer has elsewhere hinted that it may have indirectly helped to develop many of the larger one dimensional rhythms within the body—the regular movements of the viscera, for instance.

Another interesting point is made that the form of the heart-beat, the "lub dup" of the expansion and contraction, is precisely in point of time the "short long" which constitutes two-thirds of all English poetic rhythms, as well as much zoological rhythm besides. A guinea-hen's cackle, for instance, has the honor of being couched in as perfect iambics as Shakespeare's pentameters.

The parallelisms drawn throughout the article open up a wide field for speculation.

Very respectfully yours,

JOS. R. BAIRD.

1424 Master Street, Philadelphia, Pa.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-sixth Annual Meeting, held at Portland, Oregon, July 11, 12, 13 and 14, 1905.

SECTION ON SURGERY AND ANATOMY.

SECOND DAY—JULY 12TH.

(Continued from Page 189.)

Penetrating Wounds of the Abdomen.—Dr. R. Winslow, of Baltimore, Md., dealt particularly with military wounds, and stated that stab wounds are not as serious as gunshot wounds. He gave some of his personal experiences in civil practice with the results of treatment.

Dr. Cooper, of San Francisco, spoke of his experience with abdominal wounds as observed in the South African war, and called attention to the prognostic importance of an empty stomach at the time of injury.

Dr. McRae, of Atlanta, Ga., described a method of treating gunshot wounds of the abdomen, and called attention to the danger in cases where the intestine was separated from the mesentery. He was not in favor of using gallons of water to flush out the abdominal cavity after injury.

Dr. Winslow, in closing, believed that some cases should be drained, although where there had been but little contamination he did not think so.

Abdominal Crisis Caused by Meckel's Diverticulum.—Dr. Miles F. Porter, of Ft. Wayne, Ind., said that within a period of a few months there had occurred in his practice four cases of Meckel's diverticulum. In one the diverticulum caused no trouble. In the other three it was the occasion for the operation. This paper was based upon this experience, coupled with a study of reported cases (149), together with 35 cases hitherto unreported. The chief object of the paper was to add to the practical aspect of the subject. The author claimed that: Meckel's diverticulum is a fetal remnant which should but does not always disappear by a process of involution. It is present in from one to two per cent. of all individuals. It is the cause of intestinal obstruction in six per cent. of all cases. Meckel's diverticulum, when present, is a greater menace to life than is the appendix vermiformis. Of the cases tabulated, it caused obstruction by band in 101 cases, volvulus in eight cases, intussusception in twenty cases. Diverticulitis was the cause of crisis in seventeen cases, prolapse of the bowel in two cases, typhoid perforation in five cases, traumatic perforation in one and tuberculous ulceration in two cases. The diverticulum was the cause of trouble in hernia in twenty cases. It was most frequently found in umbilical hernia. One case of stricture of the gut by superinvolution of Meckel's diverticulum is reported by Maylard. Duplication of the intestine may be caused by Meckel's diverticulum. Cysts are rare, but do occur, and may produce gangrene of the bowel by traction. Illustrations were shown showing some of the numerous ways in which diverticula cause trouble. Crisis caused by Meckel's diverticulum is most apt to manifest itself as bowel obstruction or peritonitis. In 118 cases obstruction was complete and in seven incomplete. In seventeen cases there had been previous attacks of incomplete obstruction. In one case (McArthur's) the appendix vermiformis was gangrenous, because of strangulation due to Meckel's diverticulum acting as a band. Diverticulitis is likely to be diagnosticated as appendicitis. Trauma is probably a frequent cause of crisis, due to Meckel's diverticulum. Symptoms are not distinctive, and a correct diagnosis is hardly possible, nor is it necessary. A working diagnosis can be, and should be, made early. Mortality in these cases is extremely high, and is due largely to delay in operation. A Meckel's diverticulum, when met with, should be removed, whether it is causing trouble or not. It should be excised, rather than inverted, using a purse-string or Lembert suture to close the opening, owing to its size and relation to the gut. The reports of 184 cases were appended to the paper.

Dr. Jepson, of Iowa, expressed surprise that the condition was not found more frequently, and although he has been examining for the past two years every operative case he has not discovered any.

Dr. Goldspohn, of Chicago, spoke of the author's reference to the predominance of the condition on the left side and he believed it could probably be explained by the difference in the circulation of the two sides, the same as do the gynecologists.

Phlebitis, Following Abdominal and Pelvic Operations.—Dr. A. H. Cordier, of Kansas City, Mo., stated in this paper that inflammation of the saphenous or femoral vein following abdominal and pelvic operations, while of rare occurrence, is met with sufficiently often to be of much interest to surgeons en-

gaged in this class of surgery. Anatomical peculiarities of the left common, external iliac and femoral veins have been advanced as a cause of the left side so frequently becoming the seat of a phlebitis. That the left saphenous vein is the vessel most frequently involved is true, but why this vein should be the one most often affected has not been thoroughly settled. Numerous theories have been advanced, but none of them, to me, are tenable. Phlebitis of these veins follows operations performed in other parts of the body than the abdomen, as the following cases may incidentally illustrate: That the left femoral and saphenous veins are chosen fields for bacterial colonization no one will doubt after analyzing the location of the phlebitis in a large series of cases. Dr. Cordier is firmly of the opinion that these germs reach these selected points through the blood, after traversing the heart, lungs and arteries, and thus reach the walls of the veins, and that the thrombus, when one forms, is formed as a secondary process. If the walls of the vein receive the infection from the venous blood, thrombi would form earlier in the process of the inflammation, and the disease would be of more serious character in as far as permanent injury to veins is concerned. If the disease of the vein proper is secondary to the thrombus formation, as some authorities claim, there must be some anatomical arrangement favorable to the development of a thrombus in the left femoral and internal saphenous that does not exist in other veins of the body. He does not believe that the cause is to be found in the general circulation alone, the walls of the vein are primarily attacked, hence the agent producing the phlebitis must reach the vessel's walls either through arteries, lymphatics, or, if in the venous circulation, there must exist in this left vein a want of resistance to bacterial invasion that is not found in the right leg.

Isolated spots of infection of the affected vein are frequently noticed, those farthest away from the body appearing last in most instances. From this fact multiple thrombi may form in the vessel. Most of the French clinicians believe that the process is primarily an infection of the venous walls. Maurice Richardson believes that it is especially liable to follow operations in the pelvis of anemic patients, and that the disease is aseptic in its origin and in its course. In the rare instances in which the disease begins in the right leg it almost invariably will attack the left also. It was maintained for a long time that the infection in phlebitis was transported by the white corpuscles to a thrombus already formed. The infection of a femoral vein following an abdominal operation does not appear to be one of extension by continuity from the pelvic structures. In reviewing the cases he found that about 30 per cent. followed operations for the removal of the uterus for fibroids.

Pelvic Operations.—In all hysterectomies (abdominal) many ligatures are used and much tissue is compressed (later becomes necrotic), a septic cavity (uterine) is opened, and no drainage put in. The conditions left in pelvis are favorable for the development of a mild type of infection (local and constitutional) from site of "tied off" tissues. This would naturally occur about ten days or two weeks later. In vaginal operations (rarely followed by a phlebitis) the same structures are constricted, but here we get good drainage and Nature is not compelled to take care of the infected and necrotic tissues by absorption. For instance: Take two patients who are in identically the same general run-down condition; in one nature is loaded down with disposition of pedicle tissue and mild infection; in the other drainage relieves her of this added responsibility. In pyosalpinx and other suppurative processes in the pelvis an immunity has been established in the patient, so that at the time of operation she is not likely to become generally septic, many of these operations being followed by drainage. In most of my cases the first symptoms of this complication have developed in the second or third week following the operation, regardless of the character of the case operated on. If there has been any difference at all, the phlebitis has followed operations for the removal of seemingly aseptic growths, as uterine fibroids, cirrhotic ovaries and internal operations for appendicitis. It would look as though the infection was either introduced through a defective aseptic technic or was due to the absorption of the pedicle at site of the operation. To the latter theory I am disposed to lean, but this does not explain why the left vein should be most frequently involved, even though the operation was performed on the right side, as in the case in appendicitis, common-duct operations, and right oophorectomy. Some of the postoperative pneumonias are undoubtedly due to infected emboli carried from inflamed and thrombotic veins. A more fatal condition may be brought about by an emboli in the brain from the same source. Massage should not be used in the early history of the disease, for fear of dislodging fragments of a thrombus, and thus cause embolic, pulmonary or cardiac symptoms of an alarming character, or even sudden death. A patient suffering from a phlebitis should avoid all undue or violent exertion, as the detachment of a fragment of a thrombus may result in a fatal embolic injury of a cardiac or respiratory center in floor of a fourth ventricle or a multiple infection of lung or other remote organs. The acute symptoms of a phlebitis usually disappear within a few weeks under proper management, while the late history is one of a tedious recovery and the use of the elastic stocking extending over a period of months, and sometimes years. Elevation of the affected limb and bandaging it loosely and keeping it moist with witch-hazel or other cooling lotions constitutes the local treatment for the acute phlebitis. The administration of cathartics and tonics completes the treatment of ordinary cases. Later massage and the use of an elastic stocking may be necessary.

Anaerobic Cellulitis.—Dr. J. Clark Stewart, of Minneapolis, Minn., stated that, clinically, anaerobic infections have interested the medical profession since early times, as shown by the older writings. Pasteur, in 1887, made the first step toward scientific study. William Welch, in 1891, first isolated the true cause of gas infection, the *Bacillus ærogenes capsulatus*. Since this time 61 cases of surgical gas infection have been reported, with two cases being personal, and six from literature not previously collected. Personal cases, one following extravasation of urine in a patient aged seventy-one years, which recovered after free incisions, irrigation with peroxide hydrogen and wet dressings. A second case of gunshot wound died the fourth day of acute gas infection. Both cases were positively diagnosed bacteriologically. An analysis of the causation of the observed cases shows that the most prominent causes were compound fractures and bullet wounds. In all but seven of the 61 cases the disease was preceded by traumatism or surgery. The

general mortality is a little over 55 per cent., and this holds true of the mortality after compound fractures and bullet wounds. Welch has shown that the gas bacillus is very widely distributed in nature, hence gas infections are likely to be not uncommon. Gas infection from other germs is extremely improbable, and such reported cases should be scrutinized carefully.

Symptomatology.—Rational symptoms vary quite widely in the different cases. The one constant diagnostic symptom is the presence of the gas bacillus in the wound secretions, usually accompanied by emphysema of the tissues surrounding the wound of entry. Smear preparations from the wound are the most important means of early diagnosis.

Treatment.—All suspected wounds should be thoroughly cleansed, best by carbolic acid and alcohol. After diagnosis the infected area should be laid wide open by multiple incisions, and treated by continuous baths, or by irrigation and wet dressings. The use of peroxide hydrogen is theoretically indicated, and seemed of great value in one case reported. His conclusions were as follows: (1) Gas bacillus infection, while not a common disease, demands the attention of all surgeons, because, while regularly fatal when untreated, its early diagnosis is easy, and its successful treatment requires only the prompt and thorough application of well established surgical principles. (2) Either removal of entire disease by amputation or thorough exposure of its site to air and drainage seem the essentials to be attained. (3) Free incisions, the continuous bath or irrigation and wet dressings have afforded the best results, and, theoretically, hydrogen peroxide is indicated

THIRD DAY—JULY 13TH.

Extrophy of the Bladder Successfully Treated by Peter's Method.—Dr. Harry M. Sherman, of San Francisco, discussed Peter's extraperitoneal method. He compared it with Maydl's intraperitoneal method, particularly with reference to the ease of technic and the more brilliant results of the former. He said that there was urgent need for a specially constructed ureteral catheter during the operation, and pointed out a number of the dangers resulting from its use following the operation. He claimed that primary closure was preferable, although secondary closure might prove satisfactory. In conclusion he reported at length the history of a patient upon whom he had operated by this method.

Dr. E. A. Wells, of Hartford, spoke of two operations performed by Dr. Hartley, of New York, one for exstrophy of the bladder and the other for chronic tuberculous cystitis. Both operations were successful. He advised great care in the use of the ureteral catheter, and advised a technic that would permit of the doing of an operation which would preclude the opening of the peritoneal cavity.

Dr. L. L. McArthur, of Chicago, spoke of certain experiments made on lower animals by Dr. Peterson, of Ann Arbor, and Dr. Martin, of Chicago, in which they tried to implant the ureter into the rectal wall in such a manner that fecal infection could not result. He said that as a result of their studies it had developed that the fecal masses tended to empty the ureter by a suction or milking action, and thus the danger of an ascending pyelitis was entirely avoided.

Dr. Sherman, in closing the discussion, said that Dr. Hartley's method was nothing more than the regular Maydl operation He spoke of a number of experiments made by Dr. Tait and himself on the transplantation of both ureters in dogs. All of the dogs died from peritonitis, and the experimentation was abandoned. The only instance in which infection from below has occurred following operation done by Peter's method was in one patient in whom Peter kept the catheter a long time. Dr. Sherman said that the operation was simple and valuable.

Tuberculosis of the Kidney.—Dr. J. Garland Sherrill, of Louisville, Ky., considered this subject worthy of more attention than has been accorded it. Kroenlein's classification of solitary and combined tuberculosis was followed. The bacillus may gain access to the kidney through the circulation, by ascending infection from the bladder prostate, etc., or an invasion may occur from an intestinal or peritoneal tuberculosis. Cases are recorded where an empyema or a Pott's disease have caused the kidney involvement. The fact must not be overlooked that genital and renal tuberculosis may occur simultaneously and independently. Any age is susceptible to this form of the disease, but it is seen most often in the young. Statistics are confusing upon the point of sex, but it would seem that there is little difference in the frequequency with which either sex is attacked. Both kidneys are affected in two-thirds of the cases where a general tuberculosis co-exists; where the lesion is limited to the kidneys in the larger number only one kidney is affected. The kidney is diseased prior to the bladder in the large majority of cases, yet the latter organ and the ureter will in time become infected. The lesion in the kidney may be single or multiple. Tubercle as seen here does not differ from that tissue in any part of the body. It passes through the same stages and extends downward in circulatory infection and upward when the infection is from the bladder. The process is slow and some years may elapse before the secreting structure is entirely destroyed. The miliary form of the affection does not properly belong to this paper, for it is not amenable to surgical treatment. Among the complications and sequelæ mentioned in connection with this affection are hydronephrosis, fistulæ connected with the stomach or other portion of the alimentary tract or with the skin. Tuberculosis of other organs is a frequent condition.

Symptoms.—The onset of the disease is insidious, an exception being the sudden onset of pain in a previously healthy patient, probably due to the obstruction of the ureter by blood clots or cheesy plugs. Pain in the back is present, varying from soreness to a severe backache, not much influenced by motion, and radiating down the side towards the bladder. Frequent urination is one of the earliest and most prominent symptoms. This, too, in the absence of bladder involvement. The urine is acid, and contains pus, blood, albumin and casts, the latter infrequently, and tubercule bacilli. Hematuria is often one of the early symptoms of the disease, and in most cases blood can be found in the urine at some time. The blood is usually equally diffused throughout the urine, but at times the hemorrhage is severe and persistent.

The size of the kidney varies, sometimes being normal and again greatly increased in size. The presence of perirenal inflammation is likely to give the impression of a tumor. The presence of bacilli in the urine is an important but not positive sign of renal tuberculosis, as Kahlden has shown their presence in the urine without pathological changes in

the urinary tract. Bacilli, with blood and pus in the urine, in the absence of a diseased bladder or prostate, would seem to be pathognomonic. On the other hand the absence of the organisms from the urine is not a proof that the kidney is sound. Hunner advises repeated daily examinations for bacteria rather than a number of examinations upon one day, and claims that the differential stain should always be used. Tubercle bacilli were found in 15 of 22 of his cases in which a note was made. Casper found them in 80 per cent. of his cases, and confirmed the nature of the germ by cultures, and with more extended time by inoculation of guinea-pigs. Kroenlein found bacilli in 17 of 31 cases. Dr. Tilden Brown claims that cultures should be made from the urine separated by ureteral catheter, and also that inoculations are of great value. The tuberculin test seems to the writer to be of value only to establish the fact that the patient has a tuberculous lesion, the location of the focus to be determined by other means. The general symptoms are those of tuberculosis anywhere; evening rise of temperature, loss of flesh, anorexia, pallor of the skin, night sweats and perhaps edema of the feet. Later, symptoms of hectic may be present.

Diagnosis.—The diagnosis is to be made by the history, general appearance of the patient, pain less severe than that of stone, and coming on slowly as a rule, dysuria, polyuria, hematuria, pyuria in an acid urine, and the presence of albumin. The demonstration of the bacilli with the other symptoms mentioned will be conclusive. The question of the advisability of catheterizing the ureter in these cases is one worthy of some consideration. There can be no doubt of its value in making a positive diagnosis, but some objections can be offered to catheterization of a healthy ureter in the presence of disease of the other kidney, the greatest of these being the danger of infecting the healthy side. That such infection is possible we do not deny, but that it occurs with any degree of frequency we are inclined to doubt. The experiments of Albarran seem to show that disease of the ureter is only produced by local infection when there is an obstruction below the infection. Hunner, in speaking of Case II of his series, says that he thinks it fair to question whether the infection was not carried up the left ureter by the catheter eight years previously. There is certainly no sufficient proof in support of this conclusion and it would seem more reasonable to attribute the infection to the same source as the one which caused the disease of the right kidney. Albarran advises a catheter in the diseased ureter as large as it will hold, thus obstructing it, and the collection of the urine from the other kidney as it reaches the bladder. When the bladder is not extensively diseased the writer considers that catheterization of the ureter is justifiable and a means of diagnosis which is without equal. This procedure offers the most satisfactory method of determining the presence of another kidney, its functional efficiency, and the presence or absence of disease in its structure. Cryoscopy of the segregated urine will prove valuable in determining the functional power of each organ. Wright and Kilmer have proposed a new method of determining the secretory power of the kidney based upon the point at which the urine will allow complete hemolysis of a standard suspension of red blood corpuscles.

Prognosis.—The prognosis is usually unfavorable, except in circumscribed disease of one kidney, which is promptly treated by operation. The gravity is increased when both kidneys are involved, and when it occurs in the course of a general tuberculosis. It is also increased when the ureter and bladder are extensively diseased, and when other foci of the disease are present in the body. While usually progressing to an unfavorable termination, the course is often slow, and years may elapse before the fatal issue. Recovery without operation is possible, but of infrequent occurrence. E. J. Ill reports several cases of apparent recovery, and Morris says that "certain well marked cases of renal tuberculosis have been temporarily or permanently benefited, and some actually cured, by a change of residence, a suitable climate and under suitable hygienic and dietetic régime." Cases are recorded where a patient lived for some years with a diseased kidney after one had been removed. The prognosis is much improved by the early partial or complete removal of a single kidney subject to this disease. The mortality of nephrectomy was given by Gross in 1885 as 40 per cent., and by Vigneron in 1893 as 20.80 per cent., operative mortality, and 38.40 per cent., general mortality Israel places it at 18 per cent. in 1896, and Tilden Brown in 1898 at 7 per cent. Kroenlein gives his operative mortality as 5.88 per cent., and the general mortality as 29.40 per cent. The number of permanent cures is greater after complete nephrectomy, or nephro-ureterectomy, than after nephrotomy, or any other plan of treatment. Morris reports seven cases of partial nephrectomy, three of which were later subjected to total removal, while four were known to be well at considerable periods after operation. He records four nephro-ureterectomies with three recoveries and one death from hemoptysis and pulmonary tuberculosis five weeks later.

Hunner reports thirteen complete and partial operations done by Dr. Howard A. Kelly and his associates without mortality, a very favorable result.

Treatment.—We are firmly convinced that this is essentially a surgical disease when recognized while it is solitary, and only one kidney is affected, also that by conservative operation much good may result even in the later stages of the affection. In cases where operation is not accepted, or where it is deemed unwise, much good may be obtained from the measures usually employed in the treatment of tuberculosis in other parts of the organism; as good food, fresh air, suitable climate, creosote, codliver oil and some of the various tissue builders. In addition to these measures the removal of the primary focus of infection is advisable when feasible.

Dr. O. C. Smith, of Hartford, said that only after prolonged search the tubercle bacillus could be found. He collected a twenty-four-hour specimen. This he searches several times, and if the germ be not found he centrifugalizes and inoculates a guinea-pig. Cryoscopy and skiagraphy are valuable aids in diagnosis, and he commended the improved technic employed by Dr. L. G. Cole, of New York.

Dr. Maurice H. Richardson, of Boston, said that the first question to be decided in these cases is whether both kidneys were affected. A still more important problem in his opinion was whether, in the event of a proposed operation on one kidney there was a second kidney, and if so if it were eliminating properly. The only way to treat the condition under consideration, he thought, provided the integrity of the other kidney, was by total ex-

tirpation. After the removal of a tuberculous kidney, if sinuses exist that are dependent upon the tuberculous focus, he feels that the chances of a permanent cure are not worth much. In conclusion in comparison of this disease with malignant trouble he urged similar radical measures for its treatment.

Dr. Huntingdon, of San Francisco, agreed in recommending the total removal of the kidney in these cases, and referred to three patients on whom the operation had been done with excellent results. He thought that surgeons could be more optimistic in the future as regards the results of extirpation in the early stages.

Dr. C. W. Sharples, of Seattle, spoke of the importance of hemorrhage in tuberculous kidney. It might be associated, he said, with irritation of the bladder and cause painful urination, although not necessarily so. He detailed the history of a patient on whom he operated for tuberculous kidney. He died from pulmonary hemorrhage eighteen hours after operation, although evidences of any tuberculous deposit in the chest had been sought for and had not been found.

Dr. Munzen, of Wisconsin, reported having observed Dr. Mayo inject twenty drops of pure carbolic acid recently into the ureter in a case of tuberculosis of the kidney. This was done to obviate the necessity of removing the ureter.

Dr. Jacob Frank, of Chicago, spoke of the value of cystoscopy in examination of the bladder in cases of tuberculous kidney. His experience had shown him that the ureter was generally enlarged in the descending type and not the ascending type of the disease. He operates usually in two stages, and reported having opened the pleura accidentally while operating on one patient, with resulting death. It was possible, in his opinion, that death in this instance was due to the failure of the kidneys to functionate and to the presence of a stone. He also reported the history of a patient upon whom he operated sixteen years ago. He has remained comparatively well ever since, although the bladder symptoms have never subsided. He said that it is wiser if possible to make a diagnosis before the bladder had become accustomed to emptying itself so often. The bladder symptoms are then more likely to subside after operation on the kidney.

Dr. Sherrill, in closing the discussion, said that whereas it was a difficult matter to pass a catheter through an infected bladder into a sound ureter, yet he believed it could be done with safety to the patient. He thought that Dr. Mayo's method of injecting carbolic acid into the ureter provided the ureter was not very much affected was advisable at times. Dysuria and polyuria are often very early signs of much importance. Prompt search for the tubercle bacillus or for other bacteria, preferably employing many specimens, should be instituted at the earliest moment.

Treatment of Congenital Dislocation of Hip, with Report of Cases.—Dr. Park Weed Willis, of Seattle, described in full his method of reduction by gentle repeated manipulation. He said that he resorted to open incision only when, after a fair trial, manipulation had failed. He changed the casts on the affected limb with comparative frequency. The result in one patient with double dislocation was anatomically perfect. In another he was unable to maintain the reduction. In this case on making an open incision the capsule was found to be adherent across a very shallow acetabulum; reduction was performed, but the limb again getting out of position reduction became necessary. In this patient an anatomically perfect result was secured, although there was some stiffness and a slight degree of abduction. He further reported the history of a case of double dislocation with poorly developed acetabular cavities. His result in this case was anatomically perfect, while in another similar one he was able to secure anterior transposition. In conclusion he gave detailed histories of two adult patients with single and double dislocation, respectively, in which he secured a good result with comparatively slight disability.

Dr. Hunkin, of San Francisco, in discussion, said that the hip should be replaced in every case by the quickest and easiest manner possible. There is no question, he thought, about the best surgical proceeding being an open incision down to the capsule, with division of the capsule and putting the head of the bone in the acetabulum, provided there was one. The great difficulty was to keep it there. The most essential part of the operation, he believed, was wearing a splint from six to ten months, and he thought that a splint which opened at the side might be worn every night, although it had to be changed during the day.

Dr. DeForest Willard, of Philadelphia, after referring to the newspaper hysteria on this subject at the time of the visit of Dr. Lorenz, spoke against Lorenz's plan of treating these cases. He was heartily in favor of Dr. Willis' procedure of gentle manipulation provided it could be performed successfully. This he seemed inclined to doubt. He did not believe that a slight improvement in a child's walking, and particularly of men, was important compared with their beginning better prepared to do their work. He reported the results of three operations performed on three of his patients last year by Dr. Hoffa, in none of whom was a very satisfactory result obtained. In commenting on the prognosis he advised great caution, and compared the acetabulum in many cases to a tea saucer, instead of as it should be, a tea cup.

Dr. Harry M. Sherman, of San Francisco, believed that Dr. Willis had accomplished a great step in advance in the treatment of these conditions if he was able to secure and maintain the reduction by the methods he advocated. He objected on general principles to the forced manipulation of Lorenz or the bloody operation of Hoffa, and spoke in favor of the open incision.

Dr. Parker, of Portland, reported the history of a woman aged sixty years and weighing 200 pounds, who had had congenital dislocation without any other discomfort than a limp. Her oldest daughter had a similar defect on the same side; her granddaughter was perfectly sound.

Dr. James E. Moore, of Minneapolis, said that the term "bloodless operation," was a misnomer, and referred to it as the most unsurgical procedure with which he was acquainted. He believed the Lorenz manipulations often left the patients in a worse condition than they were before, and said that so far as he was concerned he would advocate open incision in the future.

Dr. S. C. Baldwin, of Salt Lake City, thought the Lorenz method a very bloody one, and did not approve of the Hoffa operation.

Dr. A. J. Ochsner, of Chicago, spoke in favor of

the Lorenz methods and reported that he had seen thirty patients operated on with good results. He believed that it was a perfectly safe and justifiable procedure. The cases, however, had to be properly selected, and the operator should understand how to do his work thoroughly. Lorenz's methods were not for the unskilled man.

Dr. Willis, in closing said that he considered the open incision an unsurgical procedure. It produced, he thought, stiff joints and crippled patients. He believed that sufficient micro-organisms enter a small opening over one hip to infect and ruin both hip joints.

Ununited Fractures in Cases of Delayed Union.—Dr. Casper W. Sharples, of Seattle, Wash., dwelt at some length on the symptoms, pathology, diagnosis, prognosis and treatment of this condition. He also gave the details of a number of cases occurring in his practice with the results of treatment in each.

Dr. Martin, of New Orleans, said that improper reduction or the interposition of tissues was responsible for many cases of ununited fracture. He advised making sure that crepitis could be elicited after reduction, this being, he thought, a sure sign of bony apposition. He was opposed to a cutting operation in these cases, and said that wire suturing was not sufficient to hold the bones. He advocated the use of a staple made of piano wire. An open drainage tube, he thought, was advisable in all of these operations.

Dr. Huntingdon, of San Francisco, believed that in almost every case delayed union was due to faulty position. The X-ray should make it possible to secure proper apposition, but he did not consider that bony crepitus as a sign was enough to decide that this result had been obtained. Fractures of the shaft of the femur are particularly liable to become misplaced owing to the large size and the tension exerted by the muscles.

Dr. Harry M. Sherman, of San Francisco, thought that injuries to the arteries was the principal cause of delayed union, or non-union, in many cases. He said that he had found that the upper fragment heals alone, and the lower fragment rarely does. Crepitus, he thought, was a satisfactory sign that the bones were in apposition. The use of the X-ray in addition was highly advisable, but spoke strongly against the X-ray being used for diagnostic purposes to the exclusion of the other methods.

Dr. Hunkin, of San Francisco, believed that the failure to secure immobility at the seat of injury was the chief factor in these misfortunes, and said that the members of the profession were afraid to put the splint on tight enough for fear of swelling, and of developing compression symptoms. He said that swelling would not take place, no matter how tight the splint, if the pressure was evenly applied.

Dr. Sharples reported, in concluding the discussion, that he had good results from the use of silver wire. Saving the periosteum was the most important factor in securing good union. When fibrous tissue was found at the ends of the bones it was to be interpreted as an attempt to heal the parts. He thought that the tearing off of the nutrient artery was an important factor, and was sure that he had seen cases of ununited fracture due entirely to that condition.

Site of Origin of Gall-Stones.—Dr. L. L. McArthur, of Chicago, reported an interesting case of gall-stones and showed the liver with the stones *in situ*. He made the observation that for several days after he had operated for all the stones in sight that they continued to come out of the wound through a drainage tube.

Dr. Maurice H. Richardson, of Boston, said that a surgeon need not reproach himself because stones came away subsequent to his operation. Observations were numerous illustrating the formation of stones in the liver instead of in the gall-bladder. In order to avoid this complication he recommended the employment of an incision large enough to admit the surgeon's hand.

Dr. Robert F. Weir, of New York, spoke of his method of securing a sufficiently large incision to enable one to thoroughly explore the liver.

Fractures of the Leg, Their Diagnosis and Treatment, With Report of Cases and Demonstration of X-Ray Pictures.—Dr. C. O. Thienhaus, of Milwaukee, presented a large number of pictures illustrating various varieties of fractures of the leg and of the foot, with his method of treatment and the results obtained.

Dr. Thienhaus said, in closing the discussion, that if a subastragaloid dislocation could not be reduced immediately the open operation should be performed, and if that was not successful the entire astragaloid must be removed.

The Section elected Dr. Robert F. Weir, of New York, Chairman, and Dr. A. C. MacLaren, of St. Paul, as Secretary; Dr. A. F. Jones, of Omaha, was elected as the delegate from the Section to the House of Delegates, and the thanks of the Section to the Rector of the First Presbyterian Church for its use for the meeting and to the retiring chairman and secretary for the excellent program were carried.

SECTION ON PRACTICE OF MEDICINE

SECOND DAY—JULY 12TH—*Continued.*

(Continued from Page 185.)

Treatment of Nephritis.—Dr. Frederick C. Shattuck, of Boston, said that drugs are absolutely powerless to affect the kidneys. Hence the necessity for treatment without medicine. The kidney in nephritis needs rest more than anything else, but absolute rest is impossible because the rest of the system would not stand it. There must, however, be just as little kidney function demanded as is possible. This limitation of the kidney function must be kept up for as long a time as is possible without injury to the individual. It is rather easy to make mistakes in the application of this rule, and, indeed, for twenty-five years almost universal acceptance of a rigid milk diet for nephritis was a mistake. The other mistaken notion was the encouragement of too much water. Water was considered to be the best diuretic, and caused a flushing out of the system. Unfortunately, however, the water did not always find its way out through the kidney, and consequently there was an increase of blood pressure which made conditions worse than they were before.

Acute Nephritis and Its Treatment.—The most important indication in acute nephritis is to enable the patient to tide over the crisis when kidney elimination is at its lowest. This can best be accomplished in previously healthy persons by absolute starvation for several days. When the kidney symptoms begin to remit, a quart of milk in the day may be allowed, and cereals and fats allowed in moderate amounts

to keep up the nutrition. There are some curious contradictions as to what is allowed patients. Some authorities absolutely prohibit alcohol, yet encourage the use of koumiss and other preparations of this kind, which contain from five to six per cent. of alcohol. The diet should be increased as the patient grows better, but animal broths should be allowed last of all, because they contain very little nutritious material and a large amount of extractives, which are decidedly irritant for the kidneys.

Acute Exacerbations of Chronic Nephritis.—These must be treated just the same as acute nephritis. Usually, however, owing to the presence of chronic nephritis for some time, the patient is not in as good condition, and consequently the starvation cannot be so absolute nor so prolonged. In all cases, however, there must be a great limitation of diet, and this must be kept up as long as possible consistently with the maintenance of the patient's strength.

Chronic Nephritis with and without Dropsy.—The studies in the pathology of the kidney have been many, yet no classification of kidney disease is entirely satisfactory, hence the necessity for using the clinical distinction in reference to dropsy. Where dropsy is present the heart is usually insufficient, and less water must be given than under other circumstances. Diuretin is an excellent aid in the diagnosis of the origin of dropsy in these cases, and, in Dr. Shattuck's experience, if taken in doses of fifteen to twenty grains three times a day, it never fails to act favorably on cardiac origin, while it has no effect on extra cardiac dropsy.

Individualization of Treatment.—Dr. Shattuck said that the most important thing in the treatment of nephritis is careful individualization. In theory a treatment may be very good, but works very bad in practice in a particular case. "What doth it profit a man if he gains good kidneys and loses his life?" Diet lists in general find their best resting place in the fire. Other organs must always be considered as well as the kidneys. The doctor must be his own prescriber of foods as well as of drugs. Common sense must be his most important guide. Von Noorden has shown that it is an error to give too much water, even in nephritis, where there is no dropsy; it leads to a strain of the left ventricle. In all cases the amount of fluid ingested must be regulated by the amount which is excreted in the urine. As soon as there is any tendency to accumulate, then the fluid taken must be lessened.

Varied Diet.—Dr. Shattuck has for some twelve years rather favored the idea of a varied diet than of too rigid a dietetic regulation. The only thing that can be said in favor of the limitation of red meat is that it limits the total amount of meat taken. After a time, if a man can take only the breast of chicken, this palls on him so much that he eats very little indeed. Dr. Shattuck allows any colored meat once a day, according to the taste of a patient, and fish and eggs at the other two meals. More kidney patients suffer from insufficient food than from too much food, once their nephritis has been discovered and their attention drawn to it. Spices should be forbidden, but all green vegetables and fresh fruits are good in season. The trouble with the treatment of kidney disease is that there has been too much dependence on half-truths. Truth is often said to be a simple matter, but, as Tom Reed said, "Half-truths are simple, but whole truths are the most complex things on God's earth."

Conclusions.—The treatment of nephritis is not by drugs, but by diet. Drugs may be used for symptoms or for the heart, but not for the kidneys. The kidneys must be spared all unnecessary work. Acute nephritis and acute exacerbations, or chronic nephritis, must be treated by starvation to the extent of a patient's strength, and the quantity of food is more important than the quality of the food, and a little alcohol can sometimes be used to decided advantage. A varied diet is better than a rigid dietary, and the amount of albumin is no guide to the diet.

Recuperative Power of Kidney.—Dr. Witherspoon, of Nashville, Tenn., said, in opening the discussion, that the most promising feature of kidney disease is the recuperative power of the kidney. The general teaching is that there is little recuperative power, yet desperate cases get better. Hence the encouragement for treatment. Much of nephritis is of the infectious and circulatory type rather than of degenerative origin. Undoubtedly the clinical condition of the patient is more important than the results of the urinary examination. There is a rush to make the diagnosis of Bright's disease not justified by our present knowledge Care is needed and many observations. In treatment the danger signals must be watched. Drugs are disappointing, but often helpful in emergencies. A varied diet keeps up the resistive power, and if the patient is not scared to death the outlook is much better than has usually been considered. If medicine be employed the diet may be neglected, yet of the two methods of treatment this is the more important.

Pathological Consideration.—Dr. Ophüls, of San Francisco, said that from the pathological side he has seen cases in which large amounts of albumin with casts were present, yet no lesion of the kidney, even microscopically, could be seen. The only thing present was congestion. This is especially likely to be true in heart cases. On the other hand, there may be acute nephritis without any symptoms in the urine. It is in subacute nephritis that most of the urinary symptoms occur. In any case repeated examinations are necessary if definite information is to be obtained. It seems evident that the eventual classification of kidney diseases will be based not on minute but on gross pathology.

Hope in Nephritis.—Dr. L. D. Bulkeley, of New York, said that he suffered from acute nephritis in 1869, and had for a time very dark-colored urine with large amounts of albumin. His symptoms continued for months, and he had to give up work. He has since had several severe attacks, one of which he had several years ago in the Yellowstone, when his urine became almost coffee-colored and had a large amount of sediment. His only treatment has been milk for a few days and then a gradual resumption of a varied diet. Notwithstanding an apparently bad diagnosis he has continued to enjoy reasonable health and has been able to accomplish a large amount of work.

Proper Use of Milk.—He considers that milk is an extremely important agent in the treatment of nephritis, but it must be taken according to definite directions. It should be taken when the stomach is quite empty, usually about an hour before meals. In Dr. Bulkeley's experience, if taken warm and slightly diluted, it never disagreed. When mixed with other foods it always disagreed with him. Dr. Bulkeley has lived through a fifteen-year term of endowment insurance in the meantime, the elder Dr. Lambert

having accepted him as a risk for that term. He has been refused life insurance by other companies, but has also been accepted by some. Albumin is present in his urine, but careful attention to his diet for a week removes it and enables him to pass the insurance examination.

Starvation of Nephritis.—Dr. McCaskey, of Indiana, said that he had been struck years ago with the fact that patients suffering from nephritis became emaciated more from limitation of their diet than from their kidney affection. Seven years ago he made a gradual return to the ordinary diet. With regard to meat his rule is that if under a meat diet the excretion of urea goes up, then meat may be allowed. A vital point in the treatment of kidney disease is the management of the gastro-intestinal tract. Kidney disease originally is due to intestinal toxins, and they must as far as possible be eliminated. Even local treatment of the stomach may be of importance in nephritis. Dr. McCaskey considers that the presence of albumin is a stronger indication of degenerative disease than the presence of casts.

Bright's Disease Systemic.—Dr. Woods Hutchinson, of Portland, Ore., said that in no department of medicine is the desecration of ancient shrines more needed for truth's sake than in nephritis. Bright's disease is not a disease of the kidney primarily, but has its origin outside of the kidney. In arterial sclerosis, interstitial nephritis is only a single localization of the arterial condition. Undoubtedly the nephritis is due to a toxemia, usually of mild degree, but producing its irritant effect over long periods. The significance of albumin in casts has been exaggerated. It is not what is found in the urine, but what is not found that is of importance. If the kidney is accomplishing its work of elimination, then all is well. It is not irritant food, such as alcohol and red meats that are to be feared, but the putrefactive processes in the intestines with the resulting poisons made ready for absorption.

Milk as a Food.—Milk is supposed to be an animal food. It is white, as the symbol of purity; hence it is supposed to be an eminently fitting food wherever toxemic processes are to be lessened. As a matter of fact, milk produces a heavier percentage of work for the kidney than almost any other. Most of the milk ordinarily consumed contains more bacteria than sewage. On the other hand, red is the color of sin. Hence, red meats must be harmful, though as a matter of fact they throw less work on the kidney than other forms of food. The greatest care must be exercised in limiting the number of bacteria in the intestinal tract. The intoxication must be diminished and the patient built up.

Tuberculosis of the Kidney.—Dr. Francine, of Philadelphia, said that in many more affections than is usually thought kidney involvement occurs. Dr. Joseph Walsh, of the Phipps Institute, of Philadelphia, has recently shown that in nearly all cases of severe tuberculosis the kidney is affected. In 34 out of 53 kidneys there were tubercles to be found in the kidney substance. Giant cells and caseation were present before this diagnosis was made. In all the other cases, at least cloudy swelling was present. The effort of the kidney to eliminate the toxins and also the bacteria of tuberculosis gives rise to this nephritic condition, which must be considered as one of the elements of severe tuberculosis.

Premonitory Nephritis.—Dr. James J. Walsh, of New York, said that the real triumphs in modern medicine have come from the early recognition of disease and the prevention of further development. In tuberculosis the mortality has been reduced because at the present time the presence of pulmonary tuberculosis is recognized long before it would have even been suspected a few years ago. In fact, many of those now admitted to sanatoria for tuberculosis would be considered as scarcely patients at all. In surgery the early recognition and intervention in appendicitis and gall-stones are producing like beneficial results. If the preliminary stage of nephritis can be recognized and care taken of patients, then a great saving of life will surely be an accomplished fact.

Premonitary Symptoms.—Dr. Walsh considers that in many cases where, because of a history of nephritis in the family, for there is no doubt that a lower resistive vitality of kidney tissues is a common matter of heredity, or where patients have suffered from scarlet fever with subsequent nephritis, or from any other infectious disease with acute kidney involvement, special attention must be paid to certain symptoms that may then be of great significance. The most important of these is heightened blood pressure with accentuation of the second heart sound. This is manifested subjectively to the patient by a fluttering heart and by tendencies to nervous arhythmia of the heart. Nearly always the cause for these will be found in a disturbance of the gastral intestinal tract, and especially tendencies to constipation. Unfortunately people have taken to treating this symptom for themselves with quack remedies of different kinds, and many of the remedies employed are such as to produce an evacuation of the lower bowel, but without any relief of the disturbed conditions within the intestine, which are causative of the constipation. If these premonitory symptoms are persistent in cases that otherwise come under suspicion of nephritis developing, then careful dietetic regulation and insistence on freedom from worrying and intellectual strain may save life for many years by taking the stress off the kidneys.

Kidney Disease as a Systemic Affection.—Dr. Frank Billings, of Chicago, said that the toxic condition which leads to nephritis exists independently of the kidney. Its effects are sometimes seen upon the eye or upon the brain before there are any kidney symptoms. A man may die from apoplexy due to Bright's disease without there having been any serious involvement of the kidney. There may be cardiovascular changes without nephritis. This condition must be treated therefore not by the indications found in the urinary symptoms, but from the clinical observations of the individual's general health.

Diagnosis of Bright's Disease.—Dr. Musser, of Philadelphia, said that the diagnosis of Bright's disease can only be made after repeated examinations of the urine and even then due consideration must be given to other symptoms. The diagnosis of Bright's disease should only be made after the patient has been in bed for some time. This is especially true in cases in which gastro-enteroptosis has been present. With regard to the urine found in autopsy, the significance of any formed elements in it cannot be considered of value, since they are the result of death processes.

Dr. Fussell, of Philadelphia, said that he wished to give a warning note with regard to urinary examinations. At times they are of dubious signifi-

cance, but they certainly prove helpful in a great majority of cases. Examinations of the urine are of importance also in affections of the heart and lungs, because they often supply the danger signal of some coming complication.

Dr. Elroy, of Nashville, Tenn., said that there had been too much confidence in urinary examinations, but they must not be disregarded. That would be a step backward. They are helpful, but their evidence must be taken in connection with other conditions. The impression derived from the present discussion may be too unfavorable to them, and cause the pendulum to swing too far to neglect of them. Classifications of kidney diseases must be made, not on morbid appearances, but on etiology. The difference in the prognosis of kidney cases is undoubtedly due in many cases to the fact that portions of the kidneys sometimes remain healthy after other parts are giving the most serious signs. Nothing is more striking than this variation in the extent of pathological appearances in kidneys when seen at autopsy.

Boiled Meats in Nephritis.—Dr. Elroy has found that boiled meats have none of the objections of roast meats. While the extractives have all been taken up by the water, all the nutritious substance of the meat is left. They are not as tasty as meats otherwise prepared, to many people, but with care any objection to them may be overcome, and then they are valuable adjuncts to the dietary. Dr. Elroy's experience with them has been most satisfactory.

Blood Pressure Increased.—Dr. Lichty, of Pittsburg, Pa., said that in sphygmomanometric absorptions the increase of blood pressure gives the earliest hint of nephritis. Undoubtedly the recognition of the toxic conditions causing the rise of blood pressure might also be possible. In blood pressure studies and bacteriology apparently the future of our knowledge of nephritis belong. Notwithstanding the extensive study of the subject, little has been discovered that is of practical value, but the outlook is encouraging.

Dr. Stengel, in closing the discussion, said that while acute interstitial nephritis is not uncommon, it never becomes inveterate, and develops chronic interstitial nephritis, though this might be expected from the names. Chronic interstitial nephritis is a cardiovascular incident. Unfortunately there are some who in the presence of the classical tripod of urinary symptoms, abundant urine of low specific gravity and some albumin think only of nephritis, and neglect the arterial condition. There can be no danger in truth rightly understood, and while it would be eminently deplorable to cease making routine examinations of the urine, it would be equally deplorable in the present state of our knowledge to continue giving an exaggerated significance to the signs found in the urine without collating them with all the other clinical conditions present in the other organs.

Dr. Brown, of San Francisco, said that with regard to the development of nephritis not only the toxins of the digestive tract must be taken into consideration, but also those of perverted function in other organs, and of disturbed metabolism generally. The thyroid and other ductless glands doubtless play an important rôle in systemic conditions that may lead to nephritis and to simulating affections.

(To be Continued.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

FIRST DAY—JULY 11TH.

Chairman's Address.—Dr. C. L. Bonifield, of Cincinnati, after expressing some well-chosen words of thanks for the honor of being made chairman of the section, spoke of the affairs and welfare of the section during the past, and of the recent progress in gynecology and obstetrics. He spoke first of the desirability of greater permanency in the office of the secretaryship, suggesting a term of not less than five years. In order to render the duties less onerous, papers should be ready for publication when read and abstracts should be furnished promptly. A limit of thirty papers in the section is suggested. Long papers should be read in abstract. As to the scope of the papers to be read before this section, he suggests that it be broadened, and that the title of the section should include Abdominal Surgery.

New Advances.—One of the most widely discussed subjects of the year has been the treatment of retrodisplacements of the uterus. That so many plans have been advocated is proof positive that no ideal method has yet been found. Many retrodisplacements cause no symptoms. When symptoms result a question arises as to the kind of treatment, surgical or otherwise. Many patients are treated surgically that might better be left alone, and vice versa, and the importance of the subject demands that some criterion of differentiation should be understood. Retrodisplacement is essentially due to disproportion of the weight of the uterus and its supports; and to remedy the condition the more normal balance must be secured either by reducing the weight or strengthning the supports. Both are attempted. Hot douches, tampons, rest, purgation in some degree accomplish the former—rest, tonics and surgery the latter. The weight may also be reduced by curettage, trachelorrhaphy, or cervix amputation. The supports may be strengthened by ventrosuspension, by Gilliam's operation, shortening the round ligaments. What cases may be treated non-surgically? In all such the uterus must be freed from adhesions and the appendages healthy and non-adherent, the posterior cul-de-sac deep and the perineum intact, so that tampons and pessaries may be effective. The time limit of treatment must be long. As to surgical methods, their great number is at times confusing. In complicated cases opening of the abdominal cavity is advisable. Here one has free scope and can better appreciate the defects and devise sensible methods of relief. Shortening the round ligaments he now performs as follows: The ligaments are stripped of their peritoneal coverings, and folded once; the folds are then stitched together with chromicized gut, the folded portion pushed through the slit in the peritoneum and the ligament stitched again toward its distal end and the peritoneum closed. He rarely trusts to shortening of the sacro-uterine ligaments.

Another problem of much interest has been cancer of the uterus. He believes that attempts at treatment are justifiable in the early stages. The early and high amputation is, in his mind, a justifiable procedure at times.

Toxemia of Pregnancy.—This subject should be reckoned among those of considerable import, and Dr. Bonifield referred to the practical results that had followed the use of the veratrum viride in treatment. The "limitation of families," or race

suicide, is also a subject that is much in discussion and in urgent need of careful study. He advocates a return to the "simple life."

Innocent Fibromyoma of Uterus.—Dr. Thos. B. Eastman, of Indianapolis, in his paper, after first noting the prevalence of the demand from many sources that all fibromyomata should be removed, on the ground that in many cases complications threatening life may result, states his belief that in a very large proportion of practically all fibroid tumors there exists in the tumor itself at the time of diagnosis, or there will develop in the tumor, other conditions which warrant their removal. Notwithstanding the fact that many undegenerated fibroids are seen at autopsy, the position taken, he believes, is justifiable. He summarized a number of references in recent literature—Camur, Cornil, Haultain, Van Franke, Smith, Fenwick, Emmett, Noble, and others, all of whom report various types of degeneration in fibroid tumors. Extensions of malignant tumors are by no means uncommon. Such instances have been reported by Schraper; extended carcinomata by Buhl, Röhrig, Cullen, Ruge, Veit, and others. Webster's lists were particularly instructive, as also those of Frederick's 788 cases.

Degeneration.—In the writer's own studies 169 cases are recorded. Thirty-one degenerations were found, as follows: necrobiotic 10, sarcomatous 1, suppurative 1, calcareous 2, myxomatous 3, adenocarcinoma 3, telangiectoma 4, cystic 7. The author then spoke of seven cases in which the histories were particularly instructive. In case one a cardiac degeneration seemed to be related to a neglected fibromyoma. A second case died, after delaying and operation, of necrobiotic degeneration. A third fibroma showed similar changes on successful removal, and a fourth, after removal, contained sarcomatous cells. Other histories were of a similar character. In all one common character was present. There was a lack of symptoms pointing to any marked pathological feature other than the tumor, and yet in all, after removal there was abundant evidence not only to justify the operation, but to show that it would have been dangerous to the life of the patient to have been guided solely by the apparent innocence of the fibromyoma. Dr. Eastman was emphatic in stating that the *laissez faire* method, because of the oncoming of the menopause, was very inadvisable.

Etiology and Treatment of So-Called Endometritis.—Dr. E. F. Tucker, of Portland, Ore., had found that in six modern classical text-books on gynecology no less than 27 varieties of endometritis were described, and to further complicate the question the authors were not sufficiently *en rapport* as to acknowledge any one variety throughout. They presented a charming combination salad of classifications founded on etiology, pathology, symptomatology, etc., etc. He expressed the hope that the younger gynecologists might be able to extricate themselves from such a tangle. After considering briefly the histology and the general pathological features of the endometrium, he went on to say that he did not believe that a true endometritis could exist apart from the direct contact of some irritant, microbic or otherwise. The endometrium was naturally involved in general uterine conditions, and one should look to an interference with the general uterine condition to correctly interpret endometrium changes. Dr. Tucker stated his disbelief in a gonorrheal endometritis. An infection of the cervical endometrium he believed in, but the endometrium of the body of the uterus does not become infection. He further expressed the hope that a more rational pathology of endometritis might result from the concerted efforts of pathologists and gynecologists.

Failure After Successful Gynecological Operations.—Dr. W. E. Gould, of Superior, Wis., in this paper defines a successful operation as the execution of a technic according to the intent of the operator and the recovery of the patient from the operative procedure *per se*, and then contrasted this definition with the question of success or failure in giving to the patient relief from the disorder for which the operation was devised. Many operations have been devised and been beautifully carried out. The operation has been a success, but the patient comes back to her physician, or to someone else, an invalid in much the same condition as before. Dr. Gould then spoke of some of the pelvic conditions in which this history was all too prevalent. The most important of these were lacerated perineum, lacerated vaginà, tearing in the pelvic floor, particularly an involvement of the puborectal muscle, which muscle should always be examined carefully after parturition. To best repair many of these conditions time is necessary, and while immediate suture after tearing may be at times advisable, he believes that a more careful and useful operation can be done later. Prolapse of the uterus and telescoping of the vagina are not unusual sequelæ of hasty repair, and genereal visceroptosis is a not infrequent accompaniment.

Retrodisplacements.—Uncomplicated retrodisplacements are usually responsible for very few symptoms, and yet at least 50 operations have been devised, and, unfortunately, performed on uncomplicated as well as complicated cases. After a preliminary course in such operative work, Dr. Gould has observed that his patients did not recover, and a more careful study of his case records showed that the pelvic floor was almost always at fault and that a movable non-infected uterus was rarely a cause of symptoms, no matter what its position; but that a fixed, injured, and infected uterus almost invariably would, irrespective of its position, normal or otherwise.

Ovarian Operations.—Conservative operations on the ovaries were another cause for failure after intrapelvic operations. Following infections the condition of the tubes and overies is always serious. If conservation of ovarian tissue is a desideratum it would best be done by a supravaginal amputation of the uterus, and an excision of the Fallopian tubes and accompanying lymphatics, rather than by doing conservative work on the ovaries alone and leaving the uterus.

SECOND DAY—JULY 12TH.

Some Cases of Unusual Type of Extra-uterine Pregnancy.—Dr. J. H. Carstens, of Detroit, Mich., gave a graphic account of two women who were sent to him within a few days of each other, by physicians who had treated them for some time under the impression that they had some inflammation, or had had a miscarriage. Both had temperature and a swelling in the side, and were in a septic condition. In one case a sac containing a four-month fetus with decomposed placenta was found adhering to the left broad ligament. In the other the operation following a diagnosis of abscess in the left broad ligament removed a quart of pus in the abscess cavity and decomposed tissue, which was recognized as placental. Both women made speedy recoveries.

Dr. Carstens expressed his amazement at what some persons could go through, and pressed home the lesson that extrauterine pregnancy is more often met with than is ordinarily expected, and pointed out the fact that the patient often unintentionally throws the doctor off his guard. His conclusion was that extrauterine pregnancy must always be in the physician's mind in cases of sudden onset of pelvic trouble; that the least irregularity of menstruation is suspicious; that inflammation and sepsis following a supposed miscarriage are often due to ruptured ectopic pregnancy, and that operation either by the vaginal or abdominal route is always indicated.

Postoperative Pelvic Exudates.—Dr. W. F. B. Wakefield, of San Francisco, spoke of the frequent occurrence of exudates following operations for pyosalpinx, hydrosalpinx, hematosalpinx, ovarian cystomata, hematomata, abscesses, and neoplasms of the uterus or peri-uterine structures. Always a thinkable condition, its practical importance seems to have been rarely emphasized. Following an observation in which a patient developed a round, orange size, fluctuating tumor, after an operation for pyosalpinx. Dr. Wakefield had studied the condition and has been led to believe that in at least 60 per cent. of the patients on whom pelvic operations are performed postoperative exudations or indurations may be found. These tumefactions are rarely observed while the patient is in bed in the hospital; it is only when a more active life is taken up that they become prominent, and then often cause as much disturbance and distress as the original complaint. He excludes those exudates that result from microbic infection, with its consequent rise in temperature, in pulse rhythm and other septic signs. Literature is almost silent concerning these exudates. The treatment of these conditions consists in local measures of hot douches, depleting tampons, and rest in the recumbent posture—preferably with the hips elevated.

Hernia of the Fallopian Tube—Without the Ovary.—Dr. Frank T. Andrews, of Chicago, makes this the subject of his paper. He reports four cases, two of which occurred in his own practice. He further offered a tabulated study of 353 cases, in which there were 42 with hernia of tube without the ovary; 76 of hernia of tube and ovary; 162 of hernia of ovary without tube; 43 of hernia of non-gravid uterus, and 30 of the pregnant uterus. Hernia of the ovary has been known almost 3,000 years. Dr. Andrews reported in detail the four cases, and had prepared a complete summary of all available reports of similar observations. No differential symptoms were reported, the condition having been found either at operation or autopsy.

Gonorrhea in the Female.—Dr. L. H. Dunning, of Indianapolis, presented a careful and exhaustive paper on this important topic. He considered the question of gonorrhea in the adult woman and its effects on her reproductive organs only. He said that he had been led to believe that the diagnosis was simple, and that the disastrous results of gonorrhea were inevitable. With reference to diagnosis, while it is true that it is easy in the acute stages, it may be extremely difficult in the chronic and subacute cases. The gonococcus becomes sequestered so completely that no refinement of technic can demonstrate its presence. The practical test of the presence of the disease in husband or lover, and the occurrence of an inflammation of the urethra, vulva, vagina or cervix in a healthy woman after intercourse is sufficient to establish a diagnosis. With reference to the topic of sterility Dr. Dunning takes issue with the report of the New York Committee of Fifteen, who state that 50 per cent. of the cases of sterility in the married woman are due to gonorrhea. He has carefully analyzed his statistics of 548 cases. An exhaustive research shows that 10 per cent. of these women were sterile, and of these one in six could he prove the presence of the gonococcus. Twenty-one per cent. of these women had made direct efforts to prevent conception, and other causes were: anteflexion 6, fibroid 11, undeveloped uterus 5, retroversion and retroflexion 4. Thus at least 45 per cent. could be definitely shown to be due to other causes than gonorrhea. In Dr. Dunning's histories 19 per cent. of the women had had only one pregnancy. The most important cause of this he had found was deliberate interference with the process of conception. The next important cause was undeveloped uterus, 27 per cent. of the patients showing this condition.

Concerning the matter of the relation of gonorrhea to pelvic disease, Dr. Dunning further contraverts the opinions expressed by the Association Committee on Prophylaxis of Venereal Disease. In 1904, of 167 operations for pelvic disorders, 27 per cent. only could be ascribed to gonorrhea—not the 80 per cent. of the Association's report. He further reported statistics of the General Hospital and the Bobb's Dispensary, in which he showed that whereas gonorrhea was common enough, and that its sequelæ were disastrous, they were not as bad as some writers would seek to maintain.

Pyosalpinx and a New Operation.—Dr. W. D. Kelly, of St. Paul, discussed the technic of a new operation for this condition, with the report of 59 cases. The author's operation is as follows: Trendelenberg position, bowels pushed back, general walling off of the abdominal cavity. The broad ligament is sought for and the finger is invaginated between the broad ligament and the mass, and the tube partially freed at distal end. The index finger is then forced between the broad ligament and the mass. A cutting needle, half curved with No. 3 pyokatnin is passed between the mass and the broad ligament onto the finger and the broad ligament is tied off. Scissors are used to sever the tissues between the broad ligament and tube. The finger is still further advanced, and an overthrow provisional suture is taken in broad ligament, which usually includes the ovarian artery. The separation of the mass is continued by the farther advancement of finger, application of another provisional suture, and the severing of the mass from the broad ligament with the scissors, a little at a time. Immediately upon dividing tissue, the provisional overthrow suture is tightened, preventing hemorrhage. A provisional Bilroth suture may be put in. The finger is still further advanced toward the uterus and broad ligament severed as before described until the horn of the uterus is reached. The omentum and bands of adhesions are tied off after the uterus is raised, an elliptical incision of tube made, and its removal is accomplished.

Fourth Report on Goldspohn Operation.—Dr. A. Goldspohn, of Chicago, contributes a further study of the results of his operation. During 1902, 1903, 1904, he had operated on 55 patients by his operation. He contends that the artificial ligament operations should be discarded; that the round ligaments are the only available means, and that the bi-inguinal

shortening of the same is the best method, and round ligament suspension the next best. He cited statistics to maintain his position.

Conservation of Normal Anatomy in Gynecology.—Dr. Daniel H. Craig, of Boston, after commenting on the wave of conservatism that has swept over the world in the matter of gynecological operations, being particularly apparent in America, develops the thesis that there is a wide field for such conservative surgery, and would extend the tendency to the fields of uterine displacements and plastic gynecologic surgery. Dr. Craig stands for a greater catholicity in operations. That there are numerous operations for a diseased condition does not argue that an ideal operation is lacking. Empiricism in surgery is to be as warmly condemned as in internal medicine. As the result of a circular letter to twelve American gynecologists, asking for comments on their own operations for uterine displacement, he found that nine found their own operation applicable to nearly all their cases. A few had modified or given up their original procedure. These results tend to confirm Dr. Craig in the opinion that good surgery would exercise a wide individual choice of operation. Dr. Craig's main contention is that a surgical procedure that follows anatomical lines is preferable to one that may accomplish a like result, but is not in accordance with anatomical principles. Thus uterine suspension by means of its natural ligaments is preferable to anchoring it to the abdominal wall.

Repair of Perineum.—Dr. G. B. Somers, of San Francisco, presented an illustrated paper on a developed technic for perineal tears.

(To be Continued.)

SECTION ON NERVOUS AND MENTAL DISEASES.

First Day—July 11th.

The meeting was called to order at 2.20 P.M. by the Chairman, Dr. J. H. McBride, Pasadena, California.

Chairman's Address.—This was read by Dr. J. H. McBride, of Pasadena, Cal. He urged that every doctor be an investigator in his daily work and stated that more had been accomplished by great physicians and surgeons than by mere experimenters. He felt that in bedside investigation much of the future advances would arise, and expressed the belief that the progress would be more in the line of preventive medicine than a therapeutic nature.

Report of the Committee on Drug Addictions.—This report was read by the Chairman, Dr. Smith Ely Jelliffe, of New York. In this report, which was of a preliminary nature only, the Committee spoke of the need for a systematization of the present knowledge concerning the various drug addictions. By reason, however, of the great number and variety of these habits the Committee had deemed it wise to restrict its suggestions to the field of the use of opium. They made several recommendations and suggested a number of topics for investigation. Among these were (1) the need for a more accurate knowledge of the distribution of the habit. Opportunities for the collection of statistical material were particularly easy of grasping by workers in jails and reformatories. Hospital statistics were of less value. (2) The psychology of the euphoria was suggested as a fruitful topic. (3) The investigation of the vassomotor control and its diseased manifestations offered another field for observation. (4) Still another avenue for research had been suggested by the work of Faust on immunity to morphine. The phenomenon of tolerance to morphine is so marked that it seems not unlikely that there must be some protective mechanism in the body that is made operative. The great dissimilarity in the cerebral structures makes it hazardous to argue from animal experimentation, but the results thus far attained make it worth while to continue the study. (5) The relation of the chemical structure to the physiological action of the allied compounds was suggested as another topic that might profitably be taken up by the members. (6) The causes for symptoms of abstention were suggested as a most fruitful line of research. Little of value has appeared along this line. The Committee was continued for another year.

Defects of Will in Practical Medicine.—This paper was read by Dr. H. T. Pershing, of Denver, Col. He said that voluntary motion is caused by the idea of the motion, which is the memory of sensations previously caused by the motion, and is in a definite kinesthetic center, connected by asociation fibers with the corresponding motor center. He dwelt at length upon the production of the processes of volition, acceleration, inhibition and deliberation and the effect of cortical exhaustion and the emotional states thereon. He detailed the method of the practical application of these principles in alcoholism, drug habits, sexual errors, neurasthenic defects and hysterical paralysis, and favored the accomplishment of the results by rewards rather than by punishments.

Dr. D. R. Brower of Chicago believed that the majority of the cases began in will disturbances, rather than mental disturbances, and that the failure to discover the inciting factor was one reason for the non-success in treatment. He emphasized the value of morphine in the treatment of these mental conditions, but its use should be without the knowledge of the patient, and properly guarded by other agents to prevent interference with elimination.

Dr. H. A. Tomlinson, of St. Peter's, Minn., stated that the inhibitory centers of the brain existed in the prefrontal region, more particularly the second and third prefrontal convulutions, and that destruction of these would interfere with this function in proportion to the extent thereof, and believed that greatest knowledge in this regard would be obtained by a closer study of the circulation of the brain as it affects elimination.

Dr. G. R. Clark, of Dearborn, Mich., referred to the various forms of dementia præcox, which, while many of them presented different clinical symptoms, from a psychological point of view, showed the same picture, and commented on the value of the previous history and origin of these cases as an aid to treatment.

Dr. J. A. Gilbert, of Portland, stated that the will was a unity and did not believe that it was possible to devise any classification of physiological psychology that is founded strictly upon a material basis.

Dr. Pershing, in closing, stated that he believed many of the perversions of the will were due to the fact that the higher development of the cortical cells had been destroyed and the mind had reverted to its primitive state.

Neurasthoid Conditions—So-Called Neurasthenia.—This paper was read by Dr. Robert Hessler, of Logansport, Ind. In it he outlined in detail the nervous symptoms produced by the inhalation of a contaminated atmosphere, which is most likely to

manifest itself upon the resident of the country coming into one of the cities to live, and in many cases a removal to a pure atmosphere will be a sufficient remedy for the condition. A number of cases were reported in detail illustrative of the position maintained in the paper.

The Localization of the Higher Psychic Functions, Especially with Reference to the Prefrontal Lobe.—Drs. Charles K. Mills and T. H. Weisenberg, of Philadelphia, presented this paper, which was read by the Secretary. The authors divided the cerebral cortex into the following areas of representation (1) sensations and movements; (2) of concrete memories; (3) of abstract concepts and higher psychic functions in general. Detailed evidence from comparative physiology and histology, physiological experiments, clinicopathological records and the study of biological principles was presented and the significance of localization of centers for speech, writing, etc., and the bearing of general on psychic localization considered in detail. The work and views of Hughlings Jackson, Ferrier, Schäfer, Phelps, Wundt and others were reviewed and commented on, and a case of lesion of the prefrontal region occurring in a man seventy-one years of age reported.

Dr. Tomlinson, of St. Peter's, Minn., stated that his personal experience confirmed that of the readers of the paper, and that the symptoms were first noticeable in that portion of the brain which had been the most active.

Dr. William House, of Portland, Ore., reported four cases illustrating the conclusions reached by the writers of the paper. In one the symptoms were due to a bullet, and in three others to foreign growths, one of a sarcomatous, and another believed to be of the carcinomatus variety.

Landry's Paralysis with Report of a Case.—This was read by Dr. Robert McGregor, of Saginaw, Mich. He discussed the influence of toxic agents and septic conditions as causal factors, and the differential diagnosis between this condition and multiple neuritis and acute anterior poliomyelitis. He reported a case occurring in a young man twenty-three years of age with a negative family and personal history, in whom there was complete paralysis of the lower and upper extremities within three days, and which after several months made a good recovery.

Types of Multiple Neuritis.—Dr. David I. Wolfstein, of Cincinnati, considered this condition under (1) toxic cases due to poisons without the body, such as alcohol, mercury, lead and arsenic; (2) similar poisons within the body due to infectious diseases, such as gonorrhea, influenza, puerperal condition, etc., (3) those due to diseased states of the body, such as rheumatism and diabetes; and (4) cases due to exposure, etc. The author reported a case illustrative of each of these groups.

Dr. H. T. Pershing, of Denver, reported the case of a metallurgist in whom the multiple neuritis was produced by arsenical poisoning. The administration of iodide of potassium markedly increased the pain, which he explained on the theory that it rendered more soluble the arsenic within the body. The man afterward made a good recovery.

Dr. Brower, Chicago, recommended the employment of large doses of quinine with strychnine to keep up the respiratory and circulatory functions in cases of multiple neuritis.

Nervous and Mental Manifestations of Pre-pernicious Anemia.—F. W. Langdon, of Cincinnati, presented this paper, which was read by the Secretary. The author called attention to the fact that a neurologic syndrome, fairly constant, with the following characteristics: (1) General ill health; (2) mental symptoms; (3) sensory disturbances, *a*, subjective, and *b*, objective; (4) Babinski's sign; (5) ataxia of gait and station; (6) diarrhea is present in a large number of cases who subsequently develop pernicious anemia. He cited the necessity for a blood examination in cases of this character, although in many instances the syndrome may precede even the microscopical evidences of the disease in the blood. He stated that the relation of impaired nervous health to blood formation may be important in a practical sense, and cited several cases illustrative of the principles laid down in his paper.

Dr. David I. Wolfstein, of Cincinnati, Ohio, did not favor the classification advanced by the author, and stated that in his experience he had seen no cases which presented such a marked clinical picture, where the condition would not have been evidenced by the blood examination, and expressed the belief that the author had included under this classification many cases that were ordinarily considered as pernicious anemia.

Dr. H. A. Tomlinson, of St. Peter's, Minn., felt that back of these cases of anemia there was an underlying auto-intoxication, which is the causative factor of the anemia and which in turn is produced by faulty elimination, the correction of which will generally remove the anemia, and that as a causative factor in the production of the nervous symptoms, we usually have a previous instability of the individual.

Periodic Paralysis.—Dr. G. E. Holtzapple, of York, Pa., read this communication, which was based upon the personal observations of the author during the past twenty-two years, of a family subject to this condition, covering four generations thereof. Six members of the family have died of this condition, and some of the members who are not subject to the paralytic attacks are the victims of periodic headaches. The paralysis in most cases begins in the lower extremities and may vary in duration from a few hours to three or four days. During the attacks none of the special senses are involved, but there is simply a loss of the power of locomotion. The attacks usually begin about puberty. The author reported in detail the physical condition of the members of the family suffering from these periodic paralyses; those suffering from periodic headaches, and those in whom no symptoms had occurred; also the results of 139 urinalyses, taken from all three classes of the cases, and a striking feature was that the paralytic group showed a marked diminution in the quantity of urea excreted.

Dr. Hilbaum suggested the value of an autopsy in the cases, and the author stated that so far this had been impossible to obtain, but that they had secured the consent of one member of the family now seventy years old to perform a post mortem at his death.

The Tabetic Foot; Its Importance in the Causation of the Ataxia of the Lower Extremities.—Paper by Drs. Sidney I. Schwab and Nathaniel Allison, of St. Louis, was read by Dr. Schwab. The paper was directed principally to the restoration of the gait in locomotor ataxia, and the methods employed and the experiments made were based upon the work done on a series of fifteen cases, extending over a period of about two years. The theories as to the causation of this condition were discussed at considerable length,

as was also the mechanics of the tabetic gait, the tabetic functional flat foot, and the hypotonic ankle joint, together with the importance of these factors in the establishment of the typical gait, with diagrams, photographs and tracings illustrative of these points. The authors then took up the efforts which they had made toward remedying the patient's manner of walking and the position of the foot and ankle. He stated that the pronation of the foot is a factor in all these cases and to its correction by mechanical appliances the physician's effort must be directed. The shoe which is employed by the authors in these cases has the sole so constructed as to counteract this pronation, and an additional assistance has been found to result from putting cleats on the sole. Several cases showing the results of this method of treatment were reported, prominent among which was that of a motorman, whose condition at the time of beginning treatment was such that he could not follow his regular occupation, but by means of the shoe he is now able to go about his customary employment for eight hours a day. The authors do not claim this to be a cure for the locomotor ataxia, but merely a mechanical correction of the gait.

Dr. H. T. Pershing, of Denver, in commenting on the value of the methods advanced by the authors, felt that anything that would enable the patient to walk even moderately well would be of very great service. He referred to the fact that a certain shoemaker was reputed to have made and sold certain shoes at an enormous price for the relief of this condition, and believed that the best results in such cases would be attained by the conjoint work of the neurologist and orthopedist, as was done by the authors of this paper.

Dr. John Punton, of Kansas City, felt that any measure which would enable the physician to relieve the gait of these patients was of great value, and that if the claims made by the authors for this method were substantiated it would certainly be welcomed by the profession as well as by the patient.

Dr. Smith Ely Jelliffe, of New York, referred to the tendency of physicians to tire of chronic nervous cases, such as patients suffering with ataxia, and believed that from this cause alone many of such patients drift into the hands of irregular practitioners. He referred to a shoemaker in New York, who had also been selling shoes at an enormous price for the remedying of this defective gait, and said that if physicians would take as much trouble as Dr. Schwab had done there would be fewer deluded tabetics in the world.

Dr. David I. Wolfstein, of Cincinnati, had also observed shoemakers attempting to correct this condition, as related by the last speaker. He believed that the work of the neurologist must of necessity go hand in hand with that of the orthopedist.

Dr. J. W. Putman, of Buffalo, believed that the greatest advance in the treatment of locomotor ataxia was made by Fraenkel when he introduced the Fraenkel movements, and felt that in conjunction with these movements the mechanical appliances were very valuable, but that without them they would be of little avail.

Dr. Schwab, in closing, stated that the treatment had not been in use a sufficient length of time to give any opinion as to its permanency. He stated that the greatest relief could be afforded to the tabetic patient's mind by correcting his gait, and that very few of them paid any attention to an Argyl-Robertson pupil or absent knee jerk, if the gait was fairly normal. He stated he did not believe this treatment had any effect upon the hypotonicity of the muscles or joints, and that the measure was advanced rather as a means of correcting the mechanical defects of gait than as a therapeutic agent.

Clinical Reports of Some Cases of Hysteria.—This paper was read by Dr. C. C. Hersman, of Pittsburg, who considered the subject under two subdivisions (1) hysterical hyperpyrexia, which is usually found in adult females between the age of eighteen and forty years, although he has observed it in males and in children as young as five years. He stated that he had observed a temperature of 118° F. in two adult females; and in a neurotic child a temperature of between 105° and 106° F. Most of these patients have violent tempers and evince but little desire to control them; and (2) hysteria agitans, which is found mostly in adults, either male or female. Either the extremities or the whole body may be involved and the motion may be either to and fro, rotary or otherwise. The body when in a supine position may perform all kinds of twitching, such as abdominal jerkings, similar to that during hiccoughs, but much more frequent, rapid facial gyrations, rubbing the feet together, falling out of bed, etc. Several illustrative cases were reported, and the author cited as an essential element in the treatment the co-operation of the patient.

Psychopathic Manifestations of the Non-insane Psychoneuroses.—Dr. John Punton, of Kansas City, in his paper said that he felt that psychology should be studied more carefully by the general practitioner than it is at the present time, and particularly by the neurologist. He felt that there were many cases which begin as minor psychoses, which, if they had been recognized in their incipiency, were susceptible of cure, and that they were also extremely susceptible to prevention . He referred particularly to the psychopathic characteristics of the clinical phenomena attending such conditions as neurasthenia, hysteria, dementia præcox, alcoholism, etc. He stated that if one made distinct classification of the neuroses and the psychoses insanity would be found in each group, and that as far as the prognosis was concerned much depended upon the early recognition and treatment. These conditions are often the forerunners of insanity if not corrected before the inhibitory influence is overwhelmed thereby. He suggested the term psychosomato-esthenia to cover many of these conditions.

Dr. H. A. Tomlinson, of St. Peter, Minn., felt that much of the discussion on this subject was mere quibbling over terms and expressed the opinion that a patient must be either sane or insane, although there may be varying degrees of the condition.

Dr. Smith Ely Jelliffe, of New York, thought the term psychoneuroses was much more preferable to denote the minor conditions than the term insanity, as it did not create the same stigma in the minds of the laity, which he felt it was unfair to thrust upon the unfortunate individual and his family. Names were not entities. Diseases themselves were not entities, particularly not those of the mind, and therefore a slavish adherence to descriptive titles was unfortunate. Nosology was a necessary evil, but in psychiatry it had been carried too far and that too much footless discussion was being carried on about words rather than things.

Dr. H. T. Pershing, of Denver, felt that the important questions to be considered were: Is the mind so changed by disease, or is it so imperfectly developed that the individual is unable to attend to the ordinary affairs of life; if it is then he is insane; if not, then he is not.

Dr. J. H. McBride, of Pasadena, Cal., stated that word insanity had a stigmatic and a distasteful significance particularly to the laity, and expressed the belief that there would be a word substituted for this term which would not convey the same idea to the laity, which would no doubt likewise in course of time assume the same meaning, when it would be necessary to substitute another.

SECOND DAY—JULY 12TH.

Public Care of the Insane.—This paper was read by Dr. J. M. Barstow, of Council Bluffs, Iowa. He gave a résumé of the laws of the various States regarding this subject, and believed that any person who was so mentally deranged as to be unable to properly care for himself or his property should be considered a ward of the State, and that when the State assumed the guardianship of such individuals, the property rights thereof should pass to the State subject to reports of the conduct there to be made to the proper tribunals at stated intervals. He felt that the States owed it to the profession and their citizens to provide laboratories and means for the clinical and pathological study of these conditions, and that the interests of the patient, as well as the public at large and the profession would be advanced thereby. He did not feel that the insane hospitals offered a suitable field for the proper investigation and study in these cases.

Dr. G. R. Clark, of Dearborn, Mich., felt that while the pathologist and histologist had been able to observe certain changes by their work in the State laboratories, there was a wide field for the clinician in these cases, referring particularly to the change in the odor from the skin and the change in the vasomotor circulation noted druing the life of these patients.

Psychosis of Morphinism.—Dr. T. D. Crothers, of Hartford, Conn., read this paper. He stated that moral paralysis was the most prominent and constant symptom, appearing in many different forms and degrees, depending on the defects of sense and feeble reasoning. The power to discriminate between true and false and right and wrong is weakened, and there is an intense desire to explain reasons and motives of conduct. The language centers suffer, and the methods of expression vary widely, being sometimes expletive, while in others violent terms, and in still others vague, doubtful terms with double meanings predominate. In a few cases criminal impulse and alternating consciousness, posing in new characters requiring mental skill and cunning, are prominent, egotism being the chief motive and prominent among the cases are swindlers, forgers, etc. Later in the career the mental strength gives away and criminal conduct and motives cannot be concealed; double personality is a mental weakness remaining during life.

Dr. John Punton, of Kansas City, Mo., discussed the subject chiefly from its medicolegal aspect and dealing particularly (1) with the ethical and (2) with the legal side of the question. He raised the question as to whether a physician would, when a patient came to him and admitted that he was a morphine habitué, and the patient was holding a position in which his condition might endanger the lives or property of others, divulge that information, citing the opinion of a leading member of the legal profession that he had no right to do so, which view was concurred in recently by the *British Medical Journal*, while the newspapers of this country took an opposite position.

Dr. G. R. Clark, of Dearborn, Mich., suggested that the acquisition of the morphine habit in epileptic patients would probably oftentimes produce the criminal manifestations and asked if the author has investigated the subject from this direction.

Dr. Crothers, in closing, stated that he had no doubt in many of these cases there was an epileptoid taint, but that why the exhaltation of reasoning along certain lines should be so prominent had not yet been determined. He cited cases illustrative of the criminal propensity, and referred to the difficulty of knowing what disposition to make of such persons when caught, expressing the belief that the appropriate place was in an institution.

Comparison of the Quick and Slow Methods of the Treatment of Morphinism.—Dr. A. J. Pressey, of Cleveland, Ohio, considered all methods in which the drug was undertaken to be withdrawn within five or six days as quick methods and where the period extended over a long time it was denominated the slow method. He stated that hyoscine hydrobromate was being much used for the rapid withdrawal of morphine in many cases, and that while the results have been apparently satisfactory in some cases, experience has shown that the danger is too great to warrant this form of treatment, believing that the patients would regain their health and strength quicker and more surely by the slow treatment, as while the withdrawal was going on, therapeutic measures could also be instituted. He stated that in many instances following the sudden withdrawal the patient's reason was deranged, and although it usually returned in periods varying from a few weeks to some months, it had in some instances been permanently affected. He cited several cases illustrative of the dangers of this rapid mode of procedure.

Dr. T. D. Crothers, of Hartford, Conn., referred to the frequency of the morphine habit among the medical profession, and expressed the belief that there was no drug which was a specific for its relief. He believed that the slow withdrawal was the most successful basis of treatment and urged the necessity for more attention to the subject in the medical colleges.

Dr. Brainard, of Los Angeles, felt that the percentage of physicians addicted to this habit was not quite as large as stated by the last speaker (10 per cent.), and Dr. Pressey, in closing, agreed with Dr. Brainard.

The Psychoses of Heart Disease.—This paper was read by Dr. William House, of Portland, Ore., which consisted chiefly of the clinical histories of 25 cases which had come under his observation in which these conditions were associated. He first classified the cases under two groups (1) slight forms, which did not produce severe mental symptoms; and (2) aggravated forms of organic disease, where the mental infirmites recorded were inferior to the physical In the severer forms, the treatment must be directed chiefly to the physical condition, while in the milder forms both may be treated coincidentally. Etiologically he divided the condition into four classes: (1) local conditions, such as palpitation, tachycardia,

etc.; (2) local pain, such as angina pectoris; (3) disturbances of the circulation, and (4) secondary lesions of the brain, giving a careful résumé of the symptomatology of each group.

The General Conditions Associated with Insanity; their Correlation and Certain Deductions.—Dr. H. A. Tomlinson, of St. Peter, Minn., read this paper, which was based upon a statistical study of 2,366 cases admitted to the St. Peter's Hospital within the past nine years. The author considered in detail the development of the human mentality from the embryologic state to its full capacity, remarking particularly upon the fact that the higher elements were the last developed, and if there was an arrest of development or defective development from any cause, it was these higher centers that suffered. And also that when the mental system was attacked by degenerative or destructive changes, it was these same highest centers, which were the last constructed, which were the first to be destroyed, and the destruction progressed in the reverse order of the development. Appended to the paper were tables showing the results of numerous analyses of the various secretions of the body, as well as examination of the blood, and the urine and other excretions. He also reported some cases in which the brain of the patient had been observed during life by means of trephined openings, and contrasted the conditions there found with those noted at the autopsy table. He did not favor the classification of Kräpelin, and believed that the therapeutic measures should be directed to the physical factors producing the irritating cause.

Dr. G. R. Clark, of Dearborn, Mich., felt that the classification of Kräpelin was one which was justified from a psychological basis. He believed that in many instances the nervous instability dated not from birth, but from conception, and suggested that possibly, if we are able to obtain a fuller knowledge of the function and pathology of the various glands, some of the problems may be cleared up.

Dr. H. G. Brainard, of Los Angeles, Cal., felt that the basis of insanity was principally two general conditions (1) nervous instability, and (2) stress, and that the question of defective metabolism played a prominent part in the production of the manifestations.

Dr. J. H. McBride, of Pasadena, Cal., referred to the classifications of insanity by Kräpelin and Dercum, and viewed that of the latter as one of the best we have. He suggested that Dercum's classification should be more generally adopted.

Dr. Tomlinson, in closing, stated that his objection to the classification of Kräpelin was that he used metaphysical terms to describe physical conditions, and that any insane patient who was observed from day to day would manifest all the symptoms described by that writer. He felt that such terms as excitement, depression and degeneration could have but one meaning, while there might be varying degrees thereof.

Officers.—The following officers of the Section were elected for the ensuing year: Chairman, Dr. Wharton Sinkler, Philadelphia. Secretary, Dr. David I. Wolfstein, Cincinnati. Executive Committee, Drs. J. H. McBride, Pasadena, Cal.; H. T. Pershing, Denver, Col., and F. W. Langdon, Cincinnati, Ohio. Member of the House of Delegates, Dr. J. H. McBride, Los Angeles, Cal.; Alternate, Dr. David I. Wolfstein, Cincinnati.

(To be Continued.)

BOOK REVIEWS.

A Treatise on the Diseases of the Nervous System. By L. Harrison Mettler, A.M., M.D., Associate Professor of Neurology, College of Medicine of the University of Illinois. Cleveland Press, Chicago.

Dr. Mettler confines his treatise to the subject-matter of neurology, thus his title needs some limitation. Psychiatry is founded on disease of the nervous system, no one can doubt. But what is in a name?

In his opening paragraph the author states that the "neuron doctrine" is now an accepted fact, but he does not state its limitations, and when he gives us a treatise in "consonance with the theory" he suffers from the weaknesses that too servile an adherence to a theory must inevitably entail.

Dr. Mettler has given us a big book—990 pages—and withal a useful one. A very distinctively personal equation shows itself throughout the volume and adds to its interest. Here is no stenographically dictated text-book from the latest German monograph, but a work bristling with the author's own observations, good and bad; logic and personalities.

His chapter on hysteria is certainly one of the best we have seen in any English text-book. He adopts the essential psychotic nature of hysteria, following the French authors closely, and is consistent in his advocacy of psychoptheraphy as the most rational type of treatment. The characterization of hypnotism, itself a hysterically induced condition, as an unsafe mode of treatment commends itself highly. The psychoneuroses throughout are illuminatingly handled and in accord with the best modern doctrines.

The author seems to have gone astray on his neuronic doctrines in separating acute anterior poliomyelitis and its closely related chronic stage of progressive muscular atrophy. It is difficult to see wherein the terminal motor neuron is not involved in both instances. Perhaps the character of the pathological process is different, but that does not interfere with the anatomical involvement.

Too much anatomy of the brain mars the second portion of the author's book. It is, we believe, better to leave the normal structures to text-books of anatomy. Otherwise the padding becomes too obvious. The anatomy might be given in outline in connection with a disease process, but *chacun à son goûte* is as indisputable in book writing as in any other intellectual pursuit.

The book as a whole is a forceful and useful volume. There are some abdominal illustrations in it, filling up many plate pages. We hope that they can be eleminated from a second edition, as they tend to impart a cheap and amateurish look to a really admirable text-book.

The American Year-Book of Medicine and Surgery for 1905. Volume—General Medicine. Edited by George M. Gould, A.M., M.D. W. B. Saunders & Company, New York, Philadelphia and London.

The American Year Book of Medicine for 1905 is a worthy addition to the already long list of editorial achievements of Dr. Gould. Having associated with him contributors of ability and authority, he has found it possible to glean from the mass of current medical literature all that is of real value and stands for scientific advancement, and consequently has been able to present to the profession a volume of the year's progress in concise form with authoritative comments.

This issue fully maintains the high standard set by the former editions and is a valuable book for those who desire a compendium of the year's work in digested form.

Pictorially it is not elaborate, though satisfactory.

THE MEDICAL NEWS.

ORIGINAL ARTICLES.

BEGINNINGS OF THE PSYCHOSES.*

BY W. K. WALKER, M.D.,

OF DIXMONT, PA.;

FIRST ASSISTANT PHYSICIAN TO THE WESTERN PENNSYLVANIA HOSPITAL FOR THE INSANE, DIXMONT, PA.

"No scientific fact is better established than this: that the functions of mind depend upon processes going on within the cells of the cortical layer of the brain." The myriad cells of which the brain is composed are supplied with an enormous quantity of blood through vessels more numerous than are distributed to any other organ; they present phenomena of nutrition, which they share in common with the other cells of the body and with the body as a whole: they receive impressions through incoming strands of minute conducting threads from every one of the fundamental cells of which the various tissues and organs are built up, and send forth impulses which govern and regulate all the functions of the latter.[1] Nowhere in the realm of organized matter is there found a more intricate physical organization than in the arrangement of the constituent cells and fibers, or nutritive functions so active as in the cortical areas of man's highest and latest developed organ. We must regard them, therefore, as representing foci of chemical phenomena among the most complex in nature.

For its specific activities of "sensitiveness" and "conductivity" brain-cell depends upon a colloidal structure so unstable of constitution that it instantly responds to the slightest vibrations of light and sound waves and the chemical influences transmitted to it by way of the organs of special sensation. More than this, it permanently incorporates in its internal structure results of these influences, as evidenced by its facilitated readiness of response to subsequent impressions of like nature.

Impressions of sensory experiences thus remaining in nervous centers are manifested as phenomena of memory. In the imprints wrought into their organization by heredity we discern "vital potentialities," or "predispositions"; in those resulting from acquired experiences (habits) we study "functional dispositions." Both are intimately bound up, therefore, with their nutritive processes.[2] Differences of internal structure, due to modifications of body fluids, from which the cell structure is built up and continually renewed, necessarily result in disturbances of function; and these are manifested by different sensations produced in individual consciousness, or by different peripheral results of these centrally acting influences.

Variable degress of vitality exist—not only in different organisms and species of organisms, but also among the different cells and tissues of which individuals are composed. This difference of vitality may be due to congenital structural defect or to inherent peculiarity of elaborating and assimilating nutrient materials, with derangement of specific activities proportional to the nutritional defect. Equally with other organs the cells entering into the formation of man's highest organ exhibit different degrees of vitality, with consequent variation of their nutritive and specific properties. Any cause lowering the nutrition of the general system is apt to be first felt by such vulnerable cells, and any slight additional stress, whether from their own functional activity, or autogenous and endogenous poisons, may suffice to bring about a maladjustment of the body forces varying in severity with the degree of inherited or acquired vulnerability of the living substance of the cortical brain areas and the conducting paths.

In this controlling and regulative mechanism which thus welds the separate units of the body into a single whole we have represented the sum-total of the body's activities; all that characterizes man as an individual, physically, mentally and morally—(for it is in the highest associative relation of cortical cells that the moral traits have their origin)—and to it also must we look for the physical basis of consciousness.

We know that consciousness, with concomitant association in memory of the body's sensory experiences, suffers profound modification as a result of the various "accidents that touch the brain." We very commonly see entire abrogation of consciousness from traumatism to the brain mass, with accompanying impairment of subsidiary brain and body functions: from damage to its structure produced by causes acting from within, such as hemorrhage, thrombosis, neoplasms and gross organic disease of its blood vessels; from the chemical influence of anesthetic and narcotic agents, such as ether, chloroform and opium; from the sudden withdrawal of oxygen as in syncope; down through the less striking, but no less unmistakable involvement by poisons acting through longer periods of time: I refer to toxins of the acute infectious diseases and the poisons of alcohol and lead, gout, rheumatism, etc. All of these are known to exert a so-called selective influence upon nerve-cell structure and to be capable of producing disturbance among the body's sensory, vasomotor, secretory and motor functions; and, also, through a loss of the quality by which impressions of past sensations are retained, a corresponding defect of the higher associative functions, that is, the power of associating ideas.

* Read at a meeting of the Pittsburg Academy of Medicine, April 11, 1905.

In our quest for disturbing factors within brain-cell mechanism we need not resort, however, to these well-known agents of destructive alteration; for Hodge and others have satisfactorily demonstrated the existence of chemical and structural changes in nerve-cell as a result of its excessive functional activity. These are earliest manifested by alteration in the nucleus, which presides over the nutritive functions of the cell, with distinctly lessened capacity for transforming incoming impressions into outgoing impulses.

Cerebral cortical cells normally exert influence by which the functional balance of both the organs and the mental faculties are maintained, without any participation of consciousness in the process. When the normal adjustment is disturbed, however, incoming impressions not only fail of proper transformation into outgoing regulative impulses, but are unduly obtruded into consciousness. Whether the maladjustment be due to congenital defect, to structural or chemical alterations from poisons, or from diminution in the amount of their food-supply, it is produced by abnormality of these cortical "machines of associative memory"; and resultant modification of their sensitiveness and conductivity is made manifest by their altered mode of responding to their habitual stimuli.

The stimuli which influence this reaction mechanism are not only those immediately acting through special sense and bodily organs, but they include the stored-up impressions from previously experienced sensations—those entering from the external world, and from his bodily processes as well—together with the correlated and mutually influencing mental states. These exist as "tendencies" to outgoing impulses and are manifested by change in subjective feeling, or outwardly exhibited objective signs, as in facial expression, pallor, blushing, etc. The individual becomes conscious of himself as a personality separate and distinct from his fellows only through these stored-up and incoming impressions; they become his "point of contact" with the world in which he lives, and, in sum-total, they constitute all that is *realized* by him. Some of these ingredients of personality can be enumerated; those, for instance, which are constantly or more frequently reproduced in memory; that is, presented to consciousness oftener than others: the visual image of the body so far as it lies in the field of vision; sensations of touch, as the contact of clothing, temperature, the positions of members, the sound of the voice, together with the sensations connected with separate parts and functions; the regular recurring appetites—hunger, thirst, sex, and the cravings and desires which, consciously or unconsciously, are associated with them; the organism's interests in regulating and subordinating these instincts and desires, or in satisfying and providing for their further gratification in consonance with civil status and with established laws, customs and conventions. Certain beliefs, ideas and social interests and cares founded upon his physical needs thus become, in the course of man's development, essential memory-constituents of his personality. In this inventory are briefly itemized some of the stimuli which, derived from many sources, constantly influence the individual organism.

These ingredients of personality are susceptible of further analysis; and they have been painstakingly studied by investigators in many fields. They are not constant in any individual, but vary with the time of life, degree of culture, inherent tendencies and immediately influencing surroundings, including among these latter the state of vitality and general health with all that these terms imply. At any given time, therefore, the consciousness of self is merely an artificial separation of those constituents of memory which occur most frequently in our perceptions. The very essence of man's personality consists of this association in memory of mutually influencing bodily sensations and mental impressions, with cortical brain cell as their meeting place. To the specific activities of this cell must we look for the explanation of normal mental phenomena; and to modifications of these activities by the processes to which cortical cell is subjected for elucidation of abnormal mental phenomena. Whether we label these latter as neurasthenic, hysteric, hydrochrondiac or insane, it is to this point they must be traced if we are adequately to comprehend and interpret them.

A feeling of health and energy with tendency to outlet in normal and customary activities is indicative of equilibrium among the brain's nutritive processes. It has been truly said that "we are not so sensible of the most robust health as we are of the least sickness." In the interplay of the sensory ingredients of mind as they occur in vigorous health, therefore, "the brain should be as non-existent for consciousness as the stomach. But the nervous sufferer has data inaccessible to his healthy fellow, and is reminded of the psychophysical connection by a thousand distressing sensations" (Strong). With any disturbance of the normal equipoise, whether from emotion, or from modification of the molecular constituents of intracellular or extracellular fluids, there are obtruded into consciousness disordered sensations of some sort; these are connected with the bodily or with the mental processes, or both.

Since functional alterations and adjustments are continually occurring among the body processes—adjustments by which the incoming impressions are correlated and harmonized with retained imprints of former sensations and images—we find in proportion as they are gradually or suddenly brought about, or act upon an unduly sensitive or unstable reactive mechanism, a resultant variation among vasomotor, secretory, and motor processes. Familiar bodily accompaniments of the emotion may be used as illustrations of this: in the pallor of fear and the livid-

ity of anger—enduring but a moment and disappearing with the cause—are demonstrated the intimate association of subjective feelings with bodily functions. And we constantly find those we regard as normal shading off into degrees which must be deemed abnormal, as measured by their intensity or their duration. Take for instance the involvement, from sudden emotion, of salivary, renal, and dermal secretions; and the more gradually induced depression of all the functions as a result of grief and anxiety. Only less apparent are transitory lapses of the appetites, with their accompanying desires, from physical exhaustion or from intense emotions; disorders of motility of stomach and intestinal walls; temporary disorders of digestion from excess, deficit, or perversion of the various secretions concerned therein, with consequent fermentation or putrefaction within the digestive canal and the production of poisons which, in turn, produce pathologic changes in the blood and resultant alterations in nutrient fluids; malnutrition of nerve centers is thus brought about, with further disturbance of the mental functions. In disorder of the sensory, secretory, excretory, and circulatory functions of the skin—"that wonderful mosaic of many organs" and "mirror of the nervous system" (to which it is so closely related in embryologic origin)—we have multiplied evidence of the organic oneness of mind and body function. Through its meshwork of minute blood vessels which respond so promptly to emotional states, we are enabled to read the innermost emotions of shame, anger, and fear as unerringly as we do some of the gastric, enteric, and toxemic disorders which are turned over to the skin-sheet for presentation.[4] From vasomotor reactions so general and excessive as to bring about altered conditions of blood pressure resulting in syncope or (if disease of the blood vessels exists) in apoplexy; or in the petechial hemorrhages observed in certain hysterical states, we have occurrences of like significance though differing so widely in character and in degree.

In the bodily resonance and reverberation to mental states of longer duration we have protean manifestations of disordered cortical activity. They may be said to include all imaginable combinations of sensory, secretory, and vasomotor disturbances, influencing, together or separately, the vegetative, organic, and motor spheres. With the frequent repetition of such states we find a tendency to groupings of reactions—to the establishment of symptom-complexes involving vulnerable and overworked organs or systems. Or, we find because of the dissipation of the brain's energies through a single channel by its excessive cortical activity or intense and rapid alternating emotions, the involvement of many functions. Depending upon the line of least resistance in a given individual, resultant maladjustment is variously exhibited: it may be in mere hypersensitiveness to the normal bodily stimuli, or in diminished resistance to pain. Notable instances of hypersensitiveness to stimuli resulting from physiological function are to be observed in sensitive women during the menstrual period associated as it is with marked changes in the body's sensory, vasomotor, and chemical processes, not to mention its emotional and mental concomitants. Most marked are the perturbations occurring at the establishment of this function and throughout the evolutional and involutional processes of the generative organs, as well as in the profound physiological changes which accompany their highest functional activity in gestation and the puerperium. Very numerous are the sensory disturbances within the pelvis which must be regarded as the effect and not the cause of pathologic nerve states.

Because of the exhaustion of certain groups of brain cells, or of their lack, or impairment of their activity from any cause, there may be an inability to attend to its multiplicity of sensory experiences, and we find those not immediately essential to the organism's existence extruded from consciousness; various enesthesias and analgesias result with associated modifications of conscious desires, appetites, and emotions. With profound duration or greater intensity, habitually excessive, perverted, or abnormal reactions to the organism's innumerable sensory stimuli become greatly facilitated; with each repetition additional traces are left in the nervous centers as memories; these become organized, so that although the original cause or causes of the abnormal reactions may be removed and the sensory and psychic accompaniments effaced, their imprints remain as functional dispositions which tend subsequently to be called into existence with greater and greater facility, and, finally, with totally inadequate external cause. Whatever be the exciting circumstance calling for readjustment of the bodily forces, attendant sensory disturbances are thrust into consciousness. The hypersensitive individual accustomed to note slight changes and habitually to select certain kinds of sensations from among the many which influence him, pays special attention to new or unusual ones thus suddenly and vividly presented to his consciousness; and, by preference, he attends to these even when they are of little intensity.

In the normal individual no one class or set of sensations continuously holds first place; they become effaced by successive states of consciousness. But while the stream of consciousness constantly varies, its changes occur in accordance with definite laws; they are determined by bodily states, and are the resultant of the sum total of impressions (retained and incoming) which influence him at that particular instant. *What* the cortical cell deals with depends upon the experiences to which it has been—and is being—subjected; *how* it deals with or transforms these sensory experiences depends upon its anatomic perfection, chemical constitution, and previous habit, consequently upon the degree of perme-

ability of its conducting paths. Viewed by the light of the physico-chemical changes to which the colloidal materials are subjected we can better comprehend the variations and vagaries in the mechanism of transformation of its sensory materials into outgoing processes, and the influence of these changes upon cortical and perceptual processes; that is, in determining what sensations shall and what shall not occupy consciousness.

All mental development is conditioned upon the retention of sensory impressions in cortical cells. Our mental representations must—in part or in entirety—be regarded as the "echoes" or reflections of the world of sensations. These reflections are, under certain conditions, susceptible of study as "after-sensations"; and painstaking investigation of these phenomena by laboratory methods has thrown much light upon the mechanism not only of normal, but of abnormal mental states. Without further going into the results of psychological studies of "vestiges of sensation," "after-sensations," and "after images" I may here state that they are closely allied to memory — and imagination-images. Their chief interest from the clinical point of view lies in the fact that not only do sensations leave more or less lasting impressions capable of subsequent revivification in memory; and that normally these vary in character with the condition of peripheral sense organ and of cerebral cells; but also that vivid sensations from abnormal processes as of pain, together with the "internal" states which originally accompanied them, are capable of like revivication in memory with the production of all their outgoing consequences, mental as well as physical; and this may result from some slight peripheral or external cause or from centrally excited processes.

The importance and far-reaching consequences of centrally excited processes, which are conditioned by the quality of "memory" inherent in nerve-cell, can not be exaggerated; for to the influence of the stored-up sensory processes associated with the vegetative and organic functions —the "organic sensations" or "feelings"—and to "the inner nerve-action that converts the functions of the senses into mental life" do we trace much that is morbid in psychic function.

In the sensitive, vulnerable, and unstable organism the slightest influence which modifies, perverts or disorders peripheral processes becomes of important significance and should never be disregarded. It is the central (cortical) process, however, that we are prone to overlook; and it is the only one in any way explanatory of the difficult clinical problems which these cases present. Of etiological significance among the conditions influencing these central processes (physicochemical and sensory)—are those known to act upon the "colloidal machines" of the cortical areas in which sensations, images, ideas, emotions, and the bodily activities are coordinated and controlled. A single persistent or dominant idea may cause maladjustment by shutting out all other ideas which otherwise might come to consciousness to exert their controlling influence, but essential even for this to an inherent vulnerability (diminished activity) of the colloidal machines of associative memory—the cortical cells. General exhaustion from any cause so limits their associative activity, and influences directly affecting them, such as fatigue, from their excessive functional activity, grief, disappointment and anxiety; also narcotics, intoxicants, and the processes are so patent that even the uninitiated may read them. Where two or more of these causes meet in their influence upon the aggregation of cells entering into the formation of the "thought organ" injurious results become proportionately intensified.

The intimate relation of after-sensations which thus result from exhausted or toxic states of cortical cells, to sensation on the one hand and to memory and imagination on the other furnishes the underlying basis of many clinical conditions or entities. Take that widespread tendency, for example, which follows eczema, and all sorts of itching eruptions, to become worse at night "just as the cortex is beginning its automatic vagaries. Night-itching would appear to be a sort of dreaming on the part of the skin, an aimless flashing hither and thither of swollen rumors of half-imaginary irritations, when the stern control of cerebral inhibition is withdrawn."[5] I can give you no better illustration of the manner in which bodily sensations are subject to elaboration under all influences limiting, modifying, or interfering with the higher cortical activity. Of like nature are many of the subjective sensations originated through the special sense of hearing, sight, etc., elaboration of sounds produced in the middle or internal ear by disease of the mucous surfaces or other parts associated therewith, or of sounds due to the impaired action of the pharyngeal muscles resulting in some unusual symptom which is brooded upon. After-images evolved from subjective visual sensations are similarly explained. The last named have been exhaustively studied with results illuminating and further explaining the influence of the mental attitude in keeping up and in elaborating symptoms which have origin in real peripheral disturbances.

The special senses are more directly associated with (because essential to) man's mental life and development than are his "organic sensations." Any deviation therefore, from the normal functioning of the former, as of after-images, becomes more apparent, and the influence of this deviation upon the mental state more readily traced. But after-images are known to exist not only for all the senses but for the emotions too; that is for the bodily reactions which, in their sum total, constitute the emotions; and these after-images are all alike produced by processes going on within the neuroplasm of brain cells, however such products may be externalized.

Their development is normally instanced in "states in which we are conscious of no particular sensation but yet are not asleep; when we are alone, in the dark, in complete silence, and oblivious of our surroundings. The experiences (sensations from the past) which are marshaled before the mental eye, mental ear, taste, smell, or touch, are quite as real (not objective, however,) as sensations themselves and play quite as important a part in our lives" (Wilfred Lay). The thrills we feel as we think of any joyous emotion; the sensations of distress or of pain as we recall a disappointment or cause for worry, anger, grief, or fear; and conversely, the feelings of emotional depression and of irritability outgrowing from exhausted and abnormal physical states, are instances which illustrate how bodily sensations shade off into emotions. Thus closely associated in the normal processes of mind the intimate relation of after-sensations with sensation on the one hand and with memory and imagination on the other is even more readily demonstrable as a result of exhausted or toxic states of the organism. Further consideration of this phase would lead us far afield in psychological and psychopathological processes and away from the object of this paper. It is sufficient to state that the normal process, as we now know it, elucidates the abnormal into which it so imperceptibly merges. Whatever the source of the original sensations of discomfort or pain, the residua or vestiges remaining in the nerve-centers play a most important part in the production of the psychoses—are the ingredients, in fact, which, further elaborated by the cortical cells, consititute the various psychoses. It must be remembered that whether as upsurging sensations of pain, or merely as hypersensitiveness to normal, unpleasant or perverted sensations, their importance is derived from the mental attitude of the sufferer toward them. In the early stage the process of elaboration goes on subconsciously, or at least, is but dimly represented in consciousness. With their frequent recurrence they more and more usurp his attention. Whether they act but momentarily or continuously bombard his consciousness, this attitude is one of frequently directing his attention toward them, or of constantly brooding upon them, so that other sensations are excluded from consciousness. Thus aggrandized in importance, subjective sensations become further elaborated and there is an attempt on the part of the patient to explain them, with the development of the multiform hypochondriacal phases we so commonly encounter.

Bodily and special sense impressions are not the only ones attended to under conditions of exhaustion, toxemia, intoxication, and disease; for associated mental sensations (images, ideas, emotions, and desires) are even more habitually presented to consciousness. Indeed, it is the emotional concomitant that is oftenest recalled to memory; and this recollection may occur long after the original sensory excitant is forgotten. Equally with sensations these mental experiences leave their vestiges or residue; and they are subject to the laws of memory and of habit as are all other nervous processes. Moreover these varying emotions are often directly traceable to the bodily sensations, as the peevishness from exhaustion and bodily pain; their functional equivalent, irritability, betokens lessened power of associative memory: that is, of marshaling before the mind's eye and coördinating and controlling mental images, ideas, emotions and instincts. In place of irritability there may be dulness resulting from the lessened facility with which cortical cells transform their impressions into outgoing impulses; this retardation of the impulse gives rise to an increased "sense of effort" which may vary from normal fatigue and exhaustion to lack of ability to think clearly or with normal rapidity, with a corresponding sense of impotence and of utter helplessness either to resist or to do.

Because of the mind's inherent tendency to cognize and recognize its experiences, whether these are of bodily sensations of well or ill-being, or of its associated special sensations, images, ideas, and emotions, they become variously combined and rearranged as a result of mutually influencing body and brain habit. The faculty of memory inherent in nerve-cell makes it possible for these experiences to be evolved or reproduced independently of external stimuli, that is, from retained impressions; this is accomplished by the imaging faculty, and the now centrally acting stimuli are capable of producing peripheral phenomena of great variety.

The character and mode of evolution of morbid mental processes vary with the cause and with inherited or acquired vulnerabilities of given cortical areas. We know that much used, overworked, organs are easily thrown out of gear; especially is this true of overworked brain tracts.[6] When we consider how delicately poised is the vasomotor regulative mechanism, how the caliber of thin-walled and yielding cortical vessels alters with ever-varying activities and emotions; how these vessels respond to excessive demands from habitual overactivity of the brain cells which they supply, we are better able to understand why peculiarities of nerve-cell activity become as one with its nutritive processes; that is, literally bound up with them. The stress from modern modes of living calls for long-continued overdilatation of cortical vessels; this condition tends more and more to permanency; there is gradually lessening resiliency of their walls which, finally, are unable to recover their normal elasticity. Sluggishness of the blood-stream results and there is consequent engorgement of lymph spaces with poisoned food materials. Impairment of the bodily secretions inevitably follows; these now exert their baneful effects, not only upon nerve-cell but also upon the delicate lining of nutrient vessels. With these definite structural conditions accounting for habitually low nutritive

processes in brain cortex and other organs there is required but slight additional poisoning, whether by alcohol, by the toxins of acute disease, rheumatism, gout, or syphilis, to lay the pathological foundations for those forms of progressive mental deterioration and insanity known to accompany gross organic disease of brain tissues and blood-vessel walls.

In these random reflections regarding a subject so vast in its ramifications I have attempted to present some of the earliest clinical data with which we must deal in our estimation of developing disorders of the mind. We know that, however sudden the irruption into consciousness of an insane idea, however abrupt its manifestation in violent deed, there is an earlier period of incubation often long in duration. Available data of this latent period are found in the patient's sensations, images, and ideas, which mark the gradual deviation from normal function. Multiform in their subjective aspect, these hidden processes present objective signs in the emotional attitudes of the patient toward his spiritual, social, or physical welfare. The outgrowth of defect in anatomic endowment at birth, or of nutritional disturbances within the body or the nerve-cells from fatigue, stress, poisons, or gross organic disease, the mechanism of their further evolution into mental disorder must be studied by the light of laws governing the special sense organs, with their neural connections, and the perceptions and apperceptions associated and correlated in memory through the instrumentality of attention; their recollection and recombination under the influence of the imaging faculty, and their known tendency toward expression in action.

The materials which are turned into morbid mental traits are the same in kind as those which constitute normal human nature. Their transformation into abnormal processes results from the "productive (though morbid) action" of cortical cells. Only as we know these mental elements and the intricate details of their mechanism as they form themselves into new associations which, through habit, become "fixed," "set," or "organized," can we grasp the pattern of morbid mental-complexes into which they are woven, and intelligently attempt to modify and transform them into physiological processes.

In approaching the study of mind by way of its ingredients, by its manner of growth and development, and its method of coördinating, readjusting, and accommodating the ever-varying bodily sensations with previously experienced and remembered impressions, and of transmuting them either into the quiet orderliness of images, ideas, beliefs, and judgments; or into conduct as exhibited in well-ordered bodily and social activities, we find that in its normal and integrative functions, as well as in its abnormal and disintegrative phases—its disorder and disease—"'tis still a man with whom we have to do of whom the conditions are wonderfully corporeal" (Montaigne).

GALVANISM AS A CURATIVE AGENT IN NERVOUS DISEASES: THE IMPORTANCE OF EQUIPMENT AND TECHNIC.[1]

BY WILLIAM BROADDUS PRITCHARD, M.D.,

OF NEW YORK;

PROFESSOR OF NEUROLOGY, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, SMITH INFIRMARY; ATTENDING NEUROLOGIST TO THE CITY HOSPITAL, ETC.

It is quite probable that both entertaining interest and educational enlightenment might result from a discussion of medical electricity along the lines of scientific and physiological interpretation. We are not yet, however, in a position, in this aspect of the subject, to do more than to reiterate old or hesitatingly advance new hypotheses, neither the old nor the new having any firmer foundation, in fact, than inductive plausibility.

Medical electricity is not yet a science. We do not know any more demonstrably or with any nearer approach to convincing accuracy than in the past, either what it is or what is its modus operandi. The scope and purpose of this paper is entirely apart from any such academic discussion. We can afford to wait with both propriety and profit until further research shall have replaced conjecture with fact. It is with the practically useful and beneficially active aspect of the subject that I shall deal. We do not know what it is or how it acts, but we do know something of what medical electricity does.

It is exclusively, too, from the standpoint of personal experience that I shall present the subject with a further restriction to a consideration of galvanism alone and in the single field of neurology. Other currents are useful in this field; faradism, the static current and quite probably the X-ray, but in much more limited degree and with far more of inconstancy in results.

Not all neurologists are in accord in estimating the value of galvanism in the treatment of nervous diseases; still less of harmonious unanimity is there as to its scope of remedial or even palliative application. By some it is esteemed as of but slight value and in an exceedingly limited field. By others it is held, with even less foundation in fact, as of widely general application and correlated curative effect. All neurologists of to-day are unanimous in according it some degree of usefulness, however limited. With such sponsors as Duchenne, Erb, Charcot, Gowers and many others, there can be no question of its legitimate place.

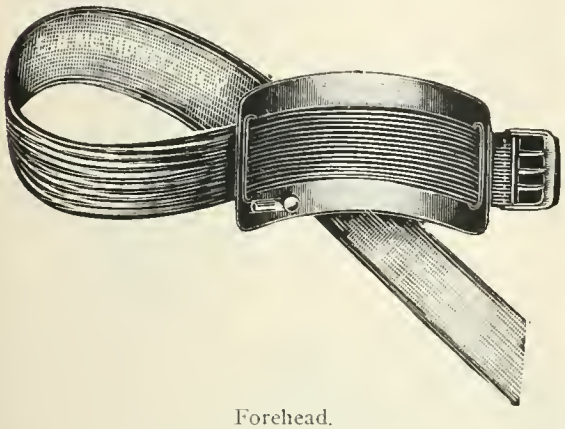
Personally I am positive in my conviction that it is an agent of demonstrable value, though by

[1] Read before New York County Medical Association, April 17, 1905.

no means indiscriminately applicable. On the contrary, its field is relatively limited, and it has no place as yet in the numerical majority of neurological cases, or, if a place at all, only as an aid in some collateral way to the end desired.

In organic central lesions with destruction of tissue, its employment, with any hope of remedial or directly curative results, constitutes an instance of the *reductio ad absurdum*. Hemiplegia, degenerative myelitis, necrotic softening from any cause, are, with rare exceptions, of this inappropriate group. Personally I have never seen any decided *propter hoc* benefit in tabes from this or any other current, although Erb recommends it as distinctly helpful in this affection. In actively inflammatory or actively irritative central diseases, as meningitis, acute myelitis or in brain tumors, it is positively and obviously contra-indicated. In the nuclear palsies, including poliomyelitis—although this disease is not usually so classified—I have never seen any specific benefit from its use, nor do I see on *a priori* grounds any rational basis for such belief.

Fig. 1.



Forehead.

It is, however, in the field of peripheral nerve diseases, including many of the neuroses, nearly all forms of neuritis, the tics, vasomotor and trophic affections, and the paresthesiæ of whatever cause, that galvanism occupies a position of positive and indispensable importance. To this group I would add, from experience, the fatigue psychoses, the headaches and cerebral conditions underlying the obsessions of neurasthenia, and of simple affective melancholia. This is really the field of selective usefulness for this agent; again and again I have seen the helmet or cincture headache of the neurasthenic, or the postcervical or occipital ache of the melancholiac, disappear as though by magic under its influence. In noting the effect on the tired headaches of neurasthenia, the simile or anology of recharging a run-down battery has often occurred to me as aptly suggestive in explaining the phenomenon of benefit or cure.

Even in this field of selection, however, galvanism is rarely, if ever, a specific. Let me further emphasize this statement: I know of no nervous affection for which electricity, or, for that matter, any other single agent is a specific. We have no specifics in neurology unless it be in tetanus or other similar diseases, which diseases are very questionably classified as neurological. Iodide of potassium will cure brain or cord syphilis very often, but the iodide is a specific for the syphilitic or metasyphilitic rather than the neurological factor in the case. Nervous function is too varied and multiple in manifestation to admit of a single measure or remedy for its restoration. Many measures may be cooperative and equally important necessities in securing a cure in a single case. Rest, environmental changes, control of morale, massage and passive exercises and assistance from drugs are among the more important and legitimate resources generally recognized. Add to these in appropriate cases galvanism and count it as of equal importance and value as an adjuvant and you have my personal estimate of its therapeutic status.

To get the best results, it is necessary to have a proper equipment and to know how to use it—a good workman and good tools are both essential to good work. Precision in dosage and a guiding principle in the method of application are just as vitally important in employing electricity as accuracy in the dosage or in the selection of appropriate media for solution or in an observance of chemical laws in drug administration. One does not guess at the dose of strychnine; one should not guess at the quantity of electricity to be given. You give large doses of quinine for one purpose and quinine in very small doses for an entirely different purpose. And yet to administer galvanism with intelligence and appropriateness and resultant benefit does not demand necessarily any special expert knowledge or elaborate equipment. A satisfactory and complete outfit, simple in construction and management, with ample current, equipped with all necessary accessories, including meter, rheostat and proper electrodes, can be obtained to-day and at a nominal cost. The accessories mentioned are absolutely essential: the meter for accurate dosage, the rheostat for perfect control

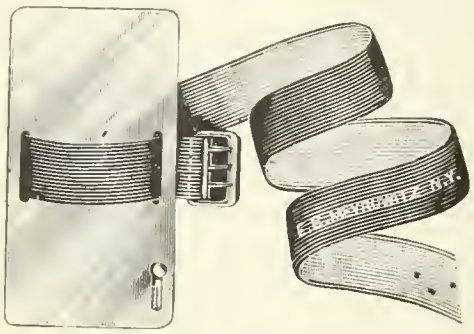
Fig. 2.

Neck.

of the current and proper electrodes to localize properly your current where needed.

It is remarkable that with an agent of acknowledged value for more than a century there should still prevail such haphazard methods and

Fig. 3.

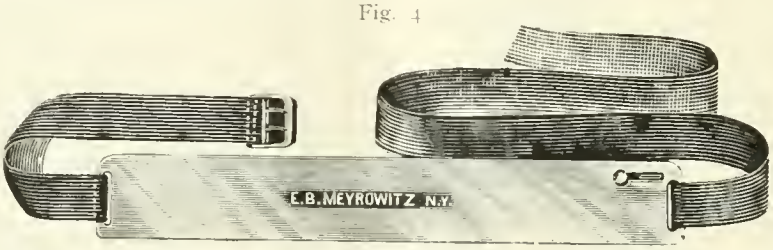


Spinal.

absolute lack of systematized technic in its use. Galvanism's stepsister, the X-ray, an infant by comparison, has been treated with far more dignified consideration: an elaborate technic and most highly specialized expertness are admittedly demanded in its employment, and yet there is far less positive evidence of important value in the records of achievement for this agent so far, whatever may be its future, as compared with galvanism. An old and familiar story to me is that of the patient who, when advised that galvanism is indicated, tells me he has used it with no benefit, that his physician had tried it or had told him to get a battery and use it himself. As well tell him to go home and operate on his own hernia or apply his own spinal brace. Inquiry revealed the fact, as a rule, that it was a faradic battery of very limited use in neurology and in many cases positively harmful and distinctly contra-indicated. If a galvanic battery, it was without meter or rheostat, leaving the patient to guess at the quantity by his sensations, an absolutely unreliable standard; and to the often harmful effects of interruptions and shock from lack of current control by the rheostat. Finally, as a crowning folly, in nineteen out of twenty instances, the electrodes furnished were those little 1 by 1 sponge-covered metal disks on the end of a stick, so familiar to you all. I know of no more farcical persistence of a palezoic relic than these little disks, and yet they are to-day the standard equipment distributed by nearly all manufacturers. This little disk has kept medical electricity, in one field at least, marking time for a hundred years. It has absolutely no place or useful purpose in your equipment; not only are they a physiological insult, they are an hygenic and an esthetic offense as well, collecting filth each time employed and becoming quickly offensive in odor and appearance. Nothing has been more effective in retarding the advancement and recognition of electrotherapeutics than the stupidity of manufacturers, although the negligence of medical men has been no inconsiderable factor.

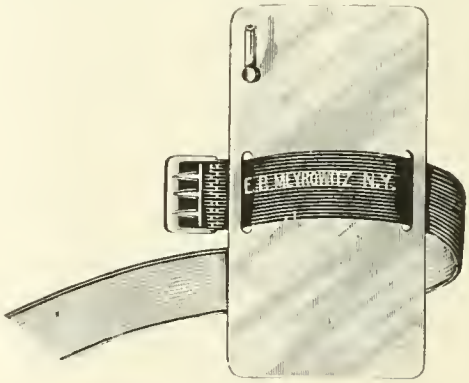
The set of electrodes which I show you represents very little of originality in conception. They are all essentially based upon the Erb electrode. Certain modifications and adaptations, however, have been evolved from experience which I believe to be of distinct practical value and importance. Briefly summarized, these modifications are as follows and for the following objects: The electrodes are made of pliant metal, permitting even adjustment to all surfaces, especially when covered. Instead of a permanent covering, I use clean towels, several times folded to a sufficient thickness, and thoroughly wet in hot water. Salt water is not necessary. The towel edge should overlap the metal to prevent burning or local concentration of the current. The electrodes are made as large as possible, in order to get a maximum of diffusion at the point of current contact, with a resulting minimum of discomfort as one object, and sometimes a maximum benefit from a

Fig. 4



Intercostal.

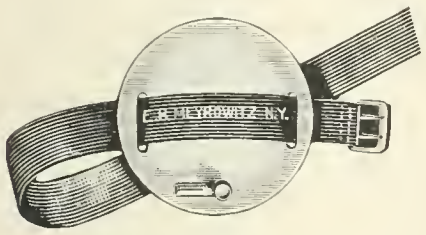
Fig. 5.



Footplate.

maximum amount of electricity for another. The smaller the electrodes the less the amount of current we can use, because of the irritant and often harmful concentration. With large electrodes also, the prolonged use of the current is easily possible. Seances of less than twenty minutes are the exception; an hour is often indicated as in old sciatica or sacrolumbar neuralgia. Most patients suffering from nervous diseases are "nervous," fidgety, restless. You must make them comfortable for the twenty minutes or the hour required. With this object, these electrodes are equipped with a strap attachment securing firm fixation, thereby insuring freedom from pain and shock from interruptions far more positively than if held by an

Fig. 6.



Hand.

attendant, whose hand, from fatigue or inattention, becomes unsteady. By this method the patient is free to change constrained and wearisome positions from time to time. He can cross his legs, put his feet on the table, handle his book or cigar, although it may be a sciatic or an ulnar or a facial nerve or a headache you are treating. Equally important is the state of mental relaxation from reassurance as to freedom from the fright and danger of shock from interruption. I have had the binding posts attached in the plane of the electrode instead of at right angles as usual, the latter making a lump which interferes with comfort. After use the electrodes are wiped dry, preventing corrosion. A set will last indefinitely.

105 West Seventh-third Street.

APPENDICITIS: MEDICAL AND SURGICAL.

BY R. R. KIME, M.D.,
OF ATLANTA, GA.;
GYNECOLOGIST TO TABERNACLE INFIRMARY.

In presenting the subject of appendicitis I am not writing for such men as Morris, Deaver, Kelly, Price, Murphy, Ochsner or the Mayos, but from the standpoint of the average surgeon and general practitioner. Such men as those mentioned, with their skill, experience and facilities, can reduce their death-rate to a point which the average surgeon throughout the country cannot. So, in discussing this question, if the appendix in the common vernacular should inquire "Where am I at?" I would say between the surgeon and general practitioner in the deep blue sea of future investigation.

It has been but a short time since the fiat of the radical surgeon was, Operate as soon as a diagnosis is made—but the present tendency is to modify that edict to some extent. Another statement equally as radical is that appendicitis has no medical treatment. The leading surgeon that operates on one or two thousand cases in one or two years sees more of the severe cases than the mild, and so it is with the prominent general practitioner whose work is mostly consultation.

Hospital cases fall under the same class. The mild cases are the ones handled first hand by the general practitioner, not deeming it necessary to call in a surgeon or send the patient to the hospital. It is self-evident to any reasoning mind that a hurried operation within the first forty-eight hours of an attack with an ascending inflammation and infection, with imperfect home surroundings or with the annoyance and anxiety incidental to transference to a hospital, will have a higher death-rate than an interval operation deliberately planned and executed. This being true it is only necessary to demonstrate that a greater number can be safely carried to the interval period. Just what the death-rate is in first attacks of appendicitis operated upon by the average surgeon or treated medically by the average physician has not been settled. From my limited observation and experience I am fully convinced that first attacks of appendicitis judiciously and properly treated will give a greater per cent. of recoveries than can be secured by the average surgeon in operating as soon as a diagnosis is made.

Understand, I do not condemn operation during the first forty-eight hours, in fact advise such when the circumstances demand it, but I do condemn as unsound and unscientific the command to operate as soon as a diagnosis is made. The assertion that appendicitis is a surgical disease and has no medical treatment is productive of much harm. I am aware that this is a surgical age, and that the American people and surgeons have appendiphobia to such a degree that it is unpopular to say a word against the surgical fad of the day. As a further evidence of this surgical tendency, we note that a medical college in the midst of us has five or six professors to teach surgical subjects, and but one to teach the unimportant subject of General Medicine. In the March, 1905, issue of *Amer. Surg. and Gyn.* are articles by different men claiming appendicitis, pneumonia and typhoid fever as surgical diseases. The surgeon is an active worker, aggressive, progressive, and seeking new fields to conquer, while it seems the general practitioner is playing the Rip Van Winkle game.

I do not condemn surgery, as I do a little of it myself, but it should be utilized in a rational, scientific way, and not swayed by radicalism to the exclusion of remedial measures that will give equally good results. If the average surgeon throughout the country operates upon every case of appendicitis as soon as a diagnosis is made, he will have a death rate of 10 to 20 per cent. depend-

ing upon his skill and surroundings. Any ordinary practitioner should be able to carry out a judicious medical treatment with a much less death rate. The expert surgeon in this line of work can operate on all cases with a death-rate of 2 to 10 per cent. The interval operation with the expert should be about .5 of one per cent. If the average surgeon would limit his work to interval operation and those with severe symptoms within the first forty-eight hours, far more lives would be saved, and much useless surgery avoided.

Dennis, New York (*American Journal of Surgery and Gynecology*), states as follows: "Dr. Richardson reports 574 interval appendectomies with no deaths; the Drs. Mayo, 1,668 interval operations with two deaths. A. C. Bernays, St. Louis, states; 'Mortality in all surgical cases, 8.5 per cent; mortality in expectant treatment, 12 to 16 per cent.'" Dr. R. T. Morris, New York, reports mortality in last 1,000 cases of two per cent.

Dr. J. B. Murphy (*American Journal of the Medical Sciences*) states: "We will admit 80 per cent. of cases recover from attack; that 20 per cent. approximately of the cases either die in the first attack or have recurrences." Dr. Deaver reports a death-rate of two per cent. in surgical treatment of 1,000 cases.

Leube's Physical Diagnosis, p. 313: "The great majority of cases (statistics vary, being about 90 per cent.) result in spontaneous recovery."

Boas' Diseases of Intestines, p. 499, says: "Sahli, Reavers, Kleinwachter, Rotter, Curschmann, Aufrecht, and others, have brought forward a very impressive material to show the curative results of conservative treatment.

"Sahli collected the entire material of Swiss physicians, thus gathering 7,213 cases. Of these, 473 were operated upon with a mortality of 21 per cent.; 6,740 were treated conservatively with a mortality of 8.8 per cent. Relapses occurred in 20.8 per cent." He also quotes—medically—"Kleinwächter's mortality 7 per cent., Curschmann and Aufrecht 4 to 5 per cent. Rotter 8.9; Renvers only 3 per cent. Surgical statistics vary from 9.6 (Murphy) to 24 per cent. Richardson's average is about 15 per cent. (Later Murphy and Richardson report a lower mortality.) He believes mortality will be decreased by increased experience, early operation, etc., but a mortality of 5 to 8 per cent. will exist in appendicitis, no matter how timely and successfully the operation is performed (Rotler)." Under internal treatment at "St. Hedwig Hospital (Berlin), of 213 cases, Rotler gives death-rate at 8.9 per cent.: Urban Hospital, Berlin), 132 cases, with a mortality of 12 per cent. (Borchardt), but of the 16 that died about 14 were admitted with inoperable general peritonitis." Some investigators report 30 to 40 per cent. of post mortems give evidence of appendicitis during life.

Ochsner has taught us that severe cases can recover without operation if properly handled. His death rate of 2.2 per cent. in 1,000 cases has demonstrated that surgery is not always essential to recovery, even in cases of perforation or gangrene of the appendix. He also states that "all cases which are diagnosed reasonably early may be carried through any acute attack, no matter what its character may be."

Another evidence of the possibility of nature properly aided handling these cases is the present tendency of many surgeons to advise waiting if the operation is not done within the first forty-eight hours, or while the infection is practically confined to the appendix. This is certainly an admission that surgery is less successful than internal treatment at this stage of the disease, or that nature, after the second day, is better able to take care of the case than the surgeon.

In arriving at our conclusions we must remember that hospital cases are not a correct guide as to results and mortality, neither are those from a consulting surgeon, nor those of the general practitioner, whose work is principally consultation. The mild case, in nearly every instance, is handled by the physician without consultation, or being sent to a hospital; thus it is many mild cases recover without operation.

From my own observation, which I hope is based upon a reasonable amount of discrimination and judgment, I would say that the general practitioner whose death-rate is above two to five per cent. in appendicitis has something wrong in his treatment of these cases. All cases of appendicitis cannot be treated alike any more than all cases of any other disease. Discrimination and judgment must be used in each case. The physician who produces active catharsis in severe cases is as dangerous or more so than the one who gives opiates and coal-tar derivatives in large does in the first stages. Mild catharsis in properly selected cases in the early stage has its benefits. Opiates in small doses, just sufficient to relieve severe pain or quiet peristalsis after a diagnosis is made, used per rectum or hypodermically, have their advantages in selected cases. Ochsner precludes all food and medicines by mouth: if vomiting is severe, he uses stomach lavage and nourishes patient by rectum, giving predigested foods in small amounts with salt solutions. Large amounts thrown into rectum excite peristalsis, which is to be avoided, especially in severe cases.

Cheyene and Burghard[1] prohibit food by mouth when vomiting is present and allow no solid food until temperature remains normal for several days. They advise salol or napthaline; they condemn purgatives, allow enemata with caution in some cases to move bowels, object to antipyretics, allow small doses of opiates guardedly in some cases, just sufficient to relieve pain, and state that belladonna and quinine will frequently relieve the pain. All agree to the use of hot or cold applications for the relief of pain.

1 Surgical Treatment, Vol. 6.

As a general line for internal treatment we would suggest the following as worthy of confidence and productive of good results, which will materially lessen the mortality in these cases.

℞ Carbolic acid ..... } aa 5ss
Papoid ..... }
Glycerin ..... } aa 5i
Listerin ..... }
Ess. Pepsin ..... g. s. 5iv

Mix. Sig. One teasponful two to four hours.

Alternate with salol-salacin carb. guiaiacol aa gr.iii, adding ⅛ to ¼ gr. of calomel.

For a mild case the above acts well, tends to disinfect the alimentary tract, lessens gas formation, quiets the stomach, fortifies nature's resisting powers and aids digestion.

In such a case salines or oil may be given or bowels flushed out in order to remove offending toxic material within first twenty-four hours. If the case is more severe, but without vomiting, and bowels not obstinate, the liquid and capsules may be continued, nourishing patient per rectum. If vomiting with severe symptoms prohibits everything by mouth, wash out stomach and give nourishment by the rectum in small quantities. Keep patient quiet in bed in every case and require use of bedpan. Opiates should be avoided in all cases as much as possible, especially until the question of operation is decided, and then given only in sufficient quantity to relieve pain and quiet peristalsis. The coal-tar derivatives are more treacherous in obscuring symptoms and depressing the patient and should not be used. No doubt our surgical friend is ready to say you cannot disinfect the alimentary canal or appendix by internal antiseptics, yet he will scrub his hands with brush, soap and antiseptics for half an hour and not render them sterile, neither can he completely sterilize the field of operation or abscess cavity, and yet he would not fail to use such means. Is not an alimentary canal distended with gas, filled with decomposing material, loaded with germs and toxins, a menace to the patient and more likely to produce unfavorable results and convert a mild into a severe form of infection?

If we cannot disinfect the alimentary canal, destroy the germs or neutralize the toxins, we can partially do so and aid nature in conserving her forces that she may be the better able to build up barriers to the invasion of the infection. The prime object in these cases should be to disinfect so far as possible the alimentary canal, remove toxic material from same when it can be done safely and early, later quieting peristalsis, avoiding drastic cathartics, depressing vitality or obscuring symptoms by opiates or coal-tar derivatives, and sustain the patient in manner least likely to do harm.

In conclusion, let me restate my position:

1. The average surgeon will save more lives by operating only on the severe cases of appendicitis within the first forty-eight hours and those that suddenly grow worse after a few days of improvement; doing the interval operation on all that do not completely recover from first attack and in relapsing cases.

2. That internal treatment properly conducted should have a death-rate of not over two to five per cent.

3. That the death-rate can be reduced nearest to zero by the average surgeon doing the interval operation on those that do not fully recover or have relapses and operating on the severe cases within the first twenty-four to forty-eight hours and those that suddenly grow worse after a few days of improvement, leaving the remainder of the cases to judicious medical treatment. There is also a field for medical treatment in many cases after appendix has been removed in correcting the original cause of appendicitis or looking after existing complications. The surgeon should not dogmatically assert that appendicitis has no medical treatment, nor decry or exclude judicious medical treatment in these cases; neither should the general practitioner exclude the surgeon, but each should assist the other.

AN ATTEMPT TO ADAPT FOR CLINICAL PURPOSES, THE TESTS FOR ELECTRIC CONDUCTIVITY OF URINE.

BY G. KOLISCHER, M.D.
AND
L. E. SCHMIDT, M.D.,
OF CHICAGO.

The development of every branch of modern surgery is marked by an endeavor to outline diagnosis, indications and prognosis as definitely and completely as possible, before undertaking the operation; so that, the result may not be marred by the shortcomings of an impromptu decision, during the interference or that the result might be simply left to good chance.

This becomes especially important if we have to deal with organs whose secretory functions are of vital importance. For a good many years the diagnostic methods have tried to keep abreast of the rather rapid development of renal surgery. There was in particular one point which concentrated the most intense attention on itself, that is, the question of the functional capacity of either kidney. In its extreme, this question will read: How are we going to determine previous to the operation whether one kidney will be sufficient to attend to the necessary eliminative process after its mate is removed.

The first preliminary problem was to collect the urine separately from either kidney. This question was solved by the introduction of the segregator and the ureteral catheter into our diagnostic armamentarium.

As to concluding from the examination of this separately collected urine upon the functional capacity of the respective kidney, it was first thought that determining the amount of urea would allow of a satisfactory decision as to the reliability of the kidney. This was very soon

refuted; and it was shown that if a test in such a direction was admissible at all, it necessarily ought to be the determination of the total amount of the solids eliminated during a certain period of time, or to express it in up-to-date language; we have to try to determine the molecular concentration of the specimen. Cryoscopy was received with the greatest enthusiasm as the method that should give infallible results in this direction; but controlling experiments soon proved that the reliability of this method was overrated, then this method was more elaborated by comparing the cryoscopy of the urine with the cryoscopic results in blood examinations; the theory was that in all cases in which both kidneys are considerably diseased, the consequence must be a decided increase of solids contained in the blood, which must lead to pronounced deviation of the freezing-point. But it was shown that cryoscopic results are not only influenced by the mistakes of art that are very likely to occur; but also by conditions under which the patient lived previous to the examination, as exercise, nourishment and so on. It furthermore was shown that a healthy kidney temporarily may be disabled to a certain extent on account of toxin brought into circulation by its diseased mate. In this way a cryoscopical examination carried out in this particular period will lead to misjudging a practically normal kidney. The most adverse and decisive criticism of the reliability of cryoscopical results was offered by Rovsing and Sockman. Without reciting all the details of the argument (we refer to their publications), we want to mention one very important objection that Rovsing makes. He says, that one of the weakest points in the recommendation of this method is that its advocates, a priori, accepted their theory as being beyond doubt, consequently they never had a chance of testing it in the converse, that is, they never extirpated a kidney if their cryoscopic results determined the other kidney as being insufficient; but Rovsing did and did it successfully.

Another attempt of determining the functional capacity of the kidneys was made by bringing certain stains into the circulation and watching their appearance in the urine. It was thought that the time that elapses between the administration of the stain and its appearance in the urine and the intensity of this staining would furnish valuable information for determining the functional capacity of the organ. But all this was refuted by Albarran, Barnard, Widal, and Vaquez. And our personal experience coincides with theirs.

Intramuscular injections of indigo-carmine did not help in improving the results in this direction.

Casper and Richter introduced the phloridzin test and claimed that it was absolutely reliable. Rovsing demonstrated in his publication that this method is also unreliable, that Casper never subjected it to the converse tests mentioned above and furthermore that the phloridzin test cannot be considered free from danger as it demonstrated by one of his own observations and by a report coming from Pielicke.

Finally the test of the electric conductivity of the urine was introduced in order to determine the functional capacity of the kidneys. This latter method is based on the experience that a normally functionating kidney will furnish a urine of higher electric resistance than would a kidney that is diseased. That this method also is not reliable, becomes apparent from the following considerations: We found that in normally individuals, normal kidneys at different times would furnish specimens of varying electric conductivity and that this variation occupied rather wide limits; we found furthermore that two normal kidneys in the same normal individual might furnish specimens of different electric conductivity, although both specimens were collected at the same time. We furthermore observe that one kidney might temporarily be impaired in its function by the presence of an infectious focus in the other kidney, that during this time the electric conductivity of the urine produced by it will be relatively high and that it will sink to a low level after the inflammatory conditions in the other are removed from the system.

In summing up, it may be said that all of the methods so far described meet with the following objections: They are all based upon the assumption that there is a general standard that represents the normal function of the kidney, that any deviation from this accepted standard indicates abnormal condition in the organ and that the degree of this deviation is in proportion with the degree of pathology. But there is not such a general valid standard. Second, none of these methods furnish a possibility of discriminating between a permanently diseased and disabled kidney and a healthy kidney that only temporarily is impaired in its function by the influence of its diseased mate.

We therefore tried to construct a method which is independent of the fallacious assumption of a general standard and which will permit the important discrimination between a permanently diseased kidney and a normal kidney only temporarily reduced in its elimination. We argued that the best way to test an organ would be to test its reaction and resistance toward the extraneous influences; we therefore endeavored to find out whether running a stain through the kidney might not influence the functional capacity of a normal and an abnormal kidney in a different way. As stain we selected indigo-carmine, and as method of testing we selected the test for electric conductivity on account of its extreme sensibility. We outlined the order of the experiments in the following manner: First, it was necessary to find out in what way, if at all, in normal kidnys, the passage of a stain would influence the electric conductivity of the urine produced. Second, it was necessary to find

out whether it would be possible to classify diseased kidneys according to the surgical question —"Can one kidney be relied upon to attend to the necessary elimination after its mate is removed?" The collection of the specimens before and after staining has to be done inside of such a short period of time that the general condition of the individual to be examined remains the same during either collection. In this way, if the expression is permitted, we made each kidney a standard unto itself. In order to get the basis for classifying the kidneys in a surgical sense, we discriminated between diseased kidneys that had produced heart and general symptoms and those that so far had not produced such symptoms. The first class, we considered as still safe in a surgical sense; while the latter were looked upon a absolutely unreliable. The results of our experiments can be summed up as follows:

After the stain appears in their secretion normal kidneys will produce urine of slightly decreased electric conductivity as compared with the conductivity of the specimen collected before the stain was administered. This decrease of conductivity, however, will never exceed nine international ohms. Even if the specimens collected from either kidney at the same time, show a difference in the electric conductivity before the stain was adminstered, the decrease of the electric conductivity after staining will be exactly the same in either specimen.

Diseased kidneys that according to the above given criterion are considered as still safe, will show in the urine collected after the stain appeared in the urine, a decided increase of electric conductivity compared with the specimen collected before administering the stain. This increase, however, will never exceed twenty international ohms.

Kidneys giving a difference of more than twenty international ohms have to be considered as entirely unsafe in a surgical sense.

A normal kidney temporarily impaired in its eliminating power by the presence of infectious foci in its mate shows the following phenomena: The specimen collected previous to the administration of the stain shows a high electric conductivity; but the decrease of electric conductivity after the adminstered stain appears in the urine never exceeds nine international ohms. Shortly after the infectious foci are eliminated from the other kidney by appropriate surgical interference, the electric conductivity of the urine furnished by the normal kidney will drop to a lower level and stay there; and again, the difference before and after stain will not exceed nine international ohms.

That this test may be considered a functional one seems to be proven by the fact that if we add indigo-carmine to a specimen in vitro there will be only a very slight change in the conductivity, a slight decrease which will never exceed two international ohms, even if so much indigo-carmine is added that the staining is by far more intense than in any case in which the stain colored the urine by passing through the kidneys.

STRICTURE OF THE URETHRA: PRELIMINARY NOTE ON A TUNNELED AND GROOVED SOUND AND A TUNNELED AND GROOVED CATHETER FOR DILATATION.

BY VICTOR COX PEDERSEN, A.M., M.D.,
OF NEW YORK;
GENITO-URINARY SURGEON TO THE OUTPATIENT DEPARTMENT OF THE NEW YORK HOSPITAL AND OF THE HUDSON STREET HOSPITAL.

Without entering into the merits or demerits of dilatation of organic stricture of the urethra as a mode of treatment, more than to say that the present tendency is directly in favor of it, it seems desirable to call attention to a sound which the writer has had in use in dispensary and private practice with the greatest possible success, for the past two and a half years. Research in the library of the Academy of Medicine and among the instrument makers has failed to reveal a sound which embodies all the features of the one to be described. Originality, however, is of far less importance than efficiency and convenience. These have certainly been reached in a most satisfactory manner, if the experience of the writer in genito-urinary work at the Outpatient Departments of the New York and Hudson Street hospitals as well as in private, is a criterion.

The features of the sound are the following, as shown in the outline drawing (Fig. 1):

1. The *curve* of the sound is of the same radius as the standard urethral sound, but one inch shorter. This decrease in length has been compensated for by an increase of one inch in the length of the shank. The object and advantage of the short curve lie in the fact that there is very much less leverage upon the face of a stricture in a short curve than in a long curve, thus the danger of injuring the filiform and of making false passages in the urethra is greatly decreased.

2. The *taper* of the curve is uniform from its base to its tip and regularly includes six sizes from No. 12 F. upward. The smallest point of the instrument is made 6 F. for the reason that this is the size of the Maisonneuve instrument. If a stricture is so tight that a 6 F. instrument cannot be engaged therein, other forms of treatment had best be adopted in the majority of cases. The small sizes, therefore, below 12 F. are uniformly at the tip No. 6 F. and regularly taper upward as follows: Two sizes for 8 F., three sizes for 9 F., four sizes for 10 F. and five sizes for 11 F. The uniformity of the taper has the object of rendering the dilatation much more secure on the following grounds: The middle of the curve of the 21 F. sound, for example, is 18 F., while the sizes 19 and 20 F. occur at equal distances between the middle of the curve and the full size of the shank. If, therefore, a No. 20 F. sound has already been passed through the stricture, the beak of a 21 F. sound will be almost entirely through the same stricture before the

dilating begins. The safety of this plan is obvious and becomes much more important when for any reason the dilating is being done more rapidly than one size at a time.

3. The *tunnel* of the sound is one third larger in diameter than the diameter of a small filiform and is five-eighths of an inch long. These dimensions are uniform throughout the set of sounds, thus securing entire uniformity of action and correcting the mistake in the standard tunneled sound by which the tunnels in the upper sizes are so large as to permit an inconvenient amount of play over the filiform. The length of the tunnel secures the sounds from twisting, buckling, breaking or cutting the filiforms, accidents which are not infrequent in the standard instrument. The length, however, is not sufficient to cause binding of the sound upon the filiform, provided ordinary skill is employed.

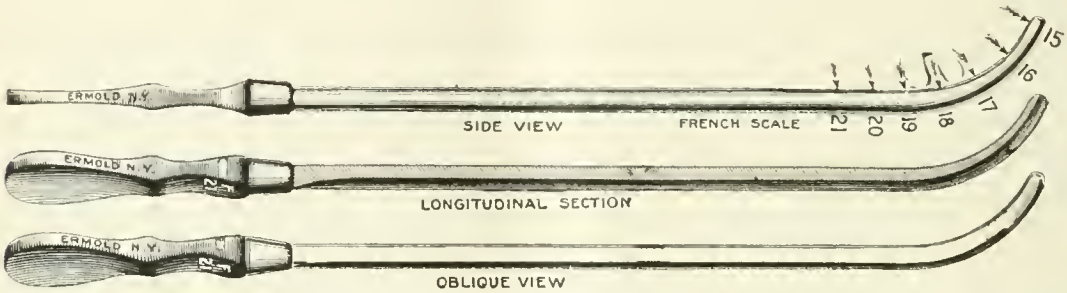
4. The *groove* of the sound passes along the shank three quarters of the length thereof, thus insuring ease of testing the freedom of the filiform. The grooves, like the tunnels, are also of the same size and length throughout the set. There is no reason whatever for increasing the width and depth thereof as the size of the sounds advances, thus the inconvenient dipping of the mucous membrane into a wide groove in a large sound is largely corrected and consequent pain to the patient avoided.

5. The tunneled and grooved silver *catheter* alluded to in the title are designed in the same manner, namely: With a short curve of uniform taper of six sizes, a shank one inch longer than the standard, tunnels of uniform diameter, five-eighths of an inch long, and grooves of uniform length, depth and width throughout the series.

6. The *set* which the author has employed consists of a 6 F., 12 F. and 18 F., tunneled and grooved catheter and sounds of all numbers from 8 to 20 F., both inclusive, also 22 and 24 F. The ordinary practitioner can do perfectly good work with catheters 6 and 12 F. and the even numbered sounds from 8 to 20 F., both inclusive. Only the specialist who is certain to encounter difficult cases frequently, needs every size of sound.

7. The *technic* of employing these instruments is as follows: After the filiform has been inserted in the usual manner, the 6 F. catheter is passed over the filiform, the bladder, if distended, is partially evacuated through the silver catheter or, if empty, is moderately filled with any mild antiseptic solution, such as boric acid, permanganate of potash, Thiersch or silver nitrate solution. The catheter is then removed, leaving the filiform in situ, and the sounds are taken in order, beginning with 8 F., and gently passed over the filiform through the stricture until that size is reached which the patient states to be moderately painful.

The writer finds that as a rule most strictures may be thus dilated to about 10 F. with very little inconvenience to the patient. The sound is then left in situ for ten or fifteen minutes in order to get the full benefit of the dilatation. After this the filiform and sound are removed and the patient is allowed to evacuate the contents of his bladder. If the contents of the bladder be urine, as in cases of distention, the sound is removed and the filiform is left in place, and the silver catheter is then again passed and the bladder carefully washed with rather hot antiseptic fluid, some of which is left in the bladder to prevent bleeding, such as sometimes occurs when an overdistended bladder is emptied. After four or five days the patient returns for the passing of larger sounds.



The side view shows the sizes of the curve from 15 F. at the tip to 21 F. at the shank; 18 F. is at the midpoint of the curve. The longitudinal section shows the relation of the tunnel and groove to each other. The oblique view foreshortens the curve and shows the roof of the tunnel, making the first five-eighths inches conical.

Usually in from four to six weeks dilatation is carried to the point where a filiform becomes unnecessary. A very few strictures are so tortuous and deeply-seated that tunneled and grooved sounds 22 and 24 F. should be passed over a filiform before use of the latter is abandoned. The writer has seen one such case in about three years of dispensary work.

This preliminary note is published with the hope that an instrument which has been so very serviceable in the hands of the writer for a long time will prove equally so in the hands of others doing genito-urinary work.

Acknowledgment is hereby made of the obligations conferred by the kindness and interest of the George Ermold Company in making these instruments.

CYSTIC KIDNEY AND LIVER.

BY HERMAN A. REQUE, A.B.,
OF CHICAGO, ILL.

(Continued from Page 214.)

The histological findings are as follows:

The lung shows the findings incident to edema and congestion, also small areas of infiltration with round cells, which are partly polymorphonuclear. The heart muscle, spleen, lymph glands and suprarenal bodies show no important changes. The liver was studied in sections taken from seven different places. In several of the sections the liver tissue appears fairly normal; in others are extensive necrotic areas containing cellular detritus, polymorphonuclear leucocytes, extravasated blood, etc. These necrotic areas are surrounded by dense round-cell infiltrations. Hyperemia, fatty changes, compressions and necrosis of liver cells, and other changes are noted. The characteristic features, however, are (1) cysts; (2) an excessive number of bile-ducts; (3) an excessive amount of fibrous tissue. These features are very unequally distributed, some sections containing scarcely any such abnormalities, while in others practically no normal tissue is found. With the exception of the largest the cysts are quite uniformly lined by a cuboidal or somewhat flattened epithelium. Where the cysts are surrounded by necrotic tissue, such as has been described, the cyst-walls are also partially disintegrated and cellular débris, blood-cells, fibrin, polymorphonuclear leucocytes, etc., are found in the cyst contents; otherwise the cysts generally contain no formed elements. The fibrous tissue is partly interlobular, but occurs also as larger masses containing cysts of various sizes, very numerous bile ducts, and here and there small foci of liver parenchyma. The excess of bile-ducts seems to be coordinate with the excess of fibrous tissue. Many of the small ducts show no lumen. Some of the ducts show several layers of epithelial cells and a few have some colloid-like material in the center of the lumen. Many of the ducts show cyst-like dilatations. There seems to be no reasonable doubt that the cysts are developed from abnormally proliferating bile-ducts; they have the same sort of epithelial lining.

The kidneys were studied in sections cut from six different places. There is considerable evidence of inflammatory processes both old and recent. Areas of round-cell infiltration, congestion, hemorrhage, and connective tissue proliferation are found; also some polymorphonuclear leucocytes; in one section a large thrombus. A great deal of sclerotic fibrous tissue is present everywhere, especially in the medulla and in the form of thick bands around the glomeruli, tubules, and cysts. The walls of the blood vessels are thickened. The glomeruli show marked changes. Some are greatly hypertrophied, others show some dilatation of Bowman's capsule, and a great many show sclerotic changes, often appearing simply as circular hyaline areas, imbedded in dense fibrous tissue or compressed between the walls of the cysts. A few appear normal.

The convoluted tubules are likewise often surrounded by dense fibrous tissue and are much compressed and distorted; but in places are small groups of convoluted tubules with no increase of interstitial tissue between them; these, however, show some degeneration of the epithelium and are considerably dilated.

A quite different appearance is presented by the straight tubules and a few of the convoluted tubules, namely a very extensive proliferation of the tubular epithelium. This is a characteristic feature and presents a variety of appearances. In some areas nearly all the tubules are completely filled with solid masses of epithelial cells and have the appearance of cords and nests of cells surrounded by fibrous tissue. These cell-masses are often much larger in diameter than any normal tubules and often have a very irregular contour with processes of cells extending into the surrounding tissue. Some tubules are lined by several layers of epithelial cells and processes of such cells partly filling the lumen. In some cases the tubules are partly filled with cells, the rest of the lumen being occupied by a homogeneous or somewhat concentrically laminated reddish or bluish-red material resembling colloid; this material seems to be a degeneration product of the epithelium and is also found in some of the smaller cysts, either in diffuse masses or as small rounded bodies like those in the tubules. The cells of the proliferating epithelium stain deeply and the nuclei are often polygonal. In numerous instances dilated tubules and cyst-like spaces contain a single layer of epithelium which is thrown into several folds so as to fill the lumen. In the dense fibrous tissue near the pelvis are numerous very narrow or distorted tubules which, however, show the same signs of proliferative activity. The lining of the pelvis seems to consist of a thick wall of sclerotic fibrous tissue.

Of the cysts the largest ones have no definite epithelial lining; the smaller ones are lined by a somewhat flattened epithelium generally of a single layer of cells. They are generally surrounded by dense, fibrous walls, in which may be found flattened glomeruli and narrow tubules without any lumen. The cyst-contents are variable. Some contain a finely granular material without any formed elements. In others we find blood-cells, polymorphonuclear leucocytes, cell-detritus of various kinds, and the above-mentioned colloid material. In rare instances short, papillary processes are seen extending into the cysts. These processes are generally covered by several layers of epithelial cells; they are found chiefly in the smaller cysts, and in these cases the whole or a part of the cyst-wall may be lined by several layers of epithelial cells, and there may be shreds of epithelium and colloid material in the cyst-contents. Such cysts are found chiefly

in the medulla. In the cortex are found a few cysts without any definite capsules, but surrounded by fairly normal renal tissue; these cysts may be described as irregular spaces having an imperfect lining of flattened cells; they may possibly represent dilated convoluted tubules or glomerular capsules. The fluid in some of the large cysts was examined chemically. It was dark red from admixture with blood. Specific gravity, 1.017. Reaction, alkaline. Albumin very abundant. Urea .22 per cent. by the Doremus method. In the sediment which mainly consists of red cells, a few leucocytes, elongated epithelial cells, and cholesterin crystals were found.

The pancreas appears to be normal, as far as the parenchyma is concerned, except for a few small groups of acini in which the cells are greatly swollen and the nuclei unstained. In the interlobular connective tissue is seen, in a few places, a peculiar development of the ducts. In part there is a great number of very small ducts; in part there are cyst-like spaces which presumably represent enlarged ducts. Some of these spaces are large enough to be seen by the naked eye; one of them measures about 3 x 1 mm. These spaces are partly lined by a high columnar epithelium, which is thrown into numerous folds so as completely to fill the interior of the spaces and also forms single-layered outgrowths of cells extending into the surrounding connective tissue. Only one small block of pancreatic tissue was preserved for examination, and it would perhaps be rather incautious to draw any definite conclusions from so incomplete a study of the organ. Nevertheless, there does seem clearly to be present an abnormal proliferative activity of the epithelium of the ducts somewhat analogous to what has been described in the liver and kidney. Pancreatic cysts have been described as occurring in connection with cystic kidney, and it is possible that they might be formed in an advanced stage of such an epithelial proliferation as is present in this case. Retention cysts might be formed through an occlusion of the ducts by the proliferation of epithelium within them, or the mass of proliferated epithelium and its degeneration products might cause cystic dilatation of the ducts.

Case II.—Miss M. V., aged nineteen years, died at the Cook Co. Hospital in August, 1902. The clinical diagnosis was typhoid hemorrhage and suspected tumor of the left kidney. The history is very meager. The young woman had the "diseases of childhood." She menstruated at sixteen, thereafter very irregularly, at one time ceasing for six months. At time of admission a hard, resistant mass, which was not tender on pressure, was palpable in the left iliac region. She was a rather small woman, but fairly well nourished.

Autopsy was held by Dr. L. M. Loeb and revealed the usual changes of typhoid fever and, in addition, bilateral cystic kidney, bilateral ureteral dilatation, distended bladder with small urethral orifice, and arteriosclerosis. The necropsy record gives the following description of the kidneys:

"The left kidney weighs 750 gms. and measures 19 x 9 x 7 cm. Its capsule strips with difficulty, leaving a surface composed of pea to walnut-sized cysts and islands of kidney tissue. On section the organ is found full of these same cysts. In the upper pole is a soft, pulpy area, 1½ cm. in diameter, which is encapsulated by a membrane. The cysts on section are found to contain a thin fluid or a yellowish, semi-solid substance. The right kidney weighs 640 gms., measures 16 x 8 x 7 cm. and presents the same condition as the left."

"The ureters are distended to the size of a lead pencil."

To the description of the kidneys may be added that all the customary markings are obliterated, there is no distinction between cortex and medulla, the pelvis is encroached upon by cysts, the partitions between many of the cysts are thin as tissue paper, often two or more cysts are only partially separated by remnants of walls, and the specimen may well be regarded as a typical example of total cystic degeneration.

The histological examination of the organs showed the usual changes of typhoid fever. The kidneys were not submitted to any special study at that time. The present histological study reveals the following:

Sections taken from four different parts of the kidneys show only slight evidence of any recent inflammation. One section contains an abscess about .5 cm. in diameter. There are also a few small areas of round-cell infiltration, considerable congestion and circumscribed areas of hemorrhage. In the cortex there are islands of fairly normal renal tissue, but the convoluted tubules generally show some degeneration of the epithelium, and there is an excess of fibrous tissue. In the medulla scarcely any normal tissue can be found, but nearly everywhere a great deal of connective tissue with large, oval nuclei, presenting often an appearance as if all the specific tissues had been reduced to a mass of indifferent, "structureless" tissue. There is also in the medulla, particularly in the region bordering on the pelvis, a great deal of more or less sclerotic tissue and a small amount of adipose tissue.

Of the glomeruli many appear normal. Many are greatly hypertrophied. Others have dilated capsule spaces, the glomeruli themselves in these cases often presenting a shrunken appearance. Some which are nearer the medulla have very irregular shapes, no definite capsules, and in some instances can scarcely be distinguished from the mass of embryonal tissue which surrounds them. Marked sclerotic changes in the glomeruli are not so frequent as in Case I. The tubules show essentially the same changes as in Case I: consider-

erable dilatation of the convoluted tubules; a striking epithelial proliferation, especially in the straight tubules, with formation of solid processes of epithelium within the tubules or extending into the interstitial tissue; compact masses of epithelium, some of which show a central degeneration suggestive of beginning cyst-formation; in the region of the papillæ mainly very narrow, or compressed and distorted, tubules, which, however, also show evidence of epithelial proliferation.

The cysts resemble those in Case I. The fibrous bands surrounding them are often very thick, and in these bands may be found a great many very slender tubules, generally with a very small, if any, lumen; these tubules often run parallel with the cyst-wall. Some larger, distorted tubules and a few flattened glomeruli are also found in the intercystic tissue; occasionally some normal renal tissue. In only one instance was anything resembling a glomerulus found within a cyst.

The two cases described are, I think, practically identical as far as the kidneys are concerned, or at least similar enough to be explained on a common basis. In reviewing the findings and seeking the primary cause of the cystic degeneration we have to consider chiefly the following possibilities: (1) Both cases show evidences of old (and recent) inflammatory processes, resulting in the production of a great excess of interstitial tissue and sclerotic degeneration, in the kidneys and in Case I also in the liver. These changes may have obstructed the excretory apparatus so as to produce retention cysts. The epithelial proliferation might then be regarded mainly as a secondary effort at regeneration or repair. (2) The epithelial proliferation may be regarded as primary and may then have produced cysts, partly by obstructing the tubules of the kidney and the bile ducts of the liver, thus causing retention of secretion, partly by the "hollowing out" of masses of proliferated epithelium and new-formed tubules and ducts. These cases would then correspond to the cyst-adenomas of Nauwerck and Hufschmied, Von Kahlden and others, and the interstitial changes might be regarded as secondary, probably due to an intercurrent inflammatory process, such as was plainly present in the liver of Case I at the time of death. (3) The malformation theory in one of its many forms might perhaps be adjusted to fit these cases. We have no evidence of any definite maldevelopment. We do have an excessive amount both of connective tissue and epithelium, the presence of which we might, with Borst, ascribe to an incoordinate development of the hypoblastic and mesoblastic elementary tissues, or, adopting Still's view, regard as the remains of embryonal elements that did not become properly differentiated.

Of these possible explanations I am inclined to adopt the second. The difficulty of differentiating, in some cases, between true neoplastic growths, as adenomas, and regenerative or hyperplastic growths is well known. However, in these cases, it is quite evident that an abnormal proliferation of epithelium is present, such as, I think, is unknown in ordinary inflammatory processes, and the belief that it has had a share, at least, in the production of cysts is, in view of the findings described, not without foundation.

Case III.[1]—These large and typic cystic kidneys were found in the body of a woman, forty-five years old, who was admitted comatose to the homeopathic service of the Cook County Hospital and died in a few hours, the diagnosis being uremia. The heart was enlarged, but there was no valvular lesion. Microscopically we note that the large cysts have dense fibrous walls with an imperfect lining of flat cells and in the contents are many colloid masses. The smaller cysts have a regular lining of short columnar cells with deeply stained nuclei; the cells may be several layers deep and there are frequent papillary outgrowths covered with one or more layers of cells and there are also masses of cells pushing out into the intercystic tissue. The smaller cysts also contain lamellated as well as coarsely granular masses. The intercystic tissue contains tubules with irregular, granular cells, with cells that have undergone colloid change, and with colloid masses. There are also fibrous, atrophic, and enlarged glomeruli. The vessels are greatly thickened in the intima and there is much increase in the connective tissue with a diffuse round-cell infiltration and small, hemorrhagic foci. The cortex and the medulla show essentially the same changes. Occasionally we come upon islands of cells in the intercystic tissue that are independent of cysts, have nuclei with much chromatin, the cells being sometimes arranged in a circle as though to form a cyst. This brief summary indicates two processes—a progressive formation of cysts as in cystadenoma elsewhere and a chronic and acute interstitial nephritis in the intercystic renal remnants.

Case IV.—The patient was a middle-aged woman who for years complained of a swelling in the region of the liver and finally died suddenly from a cerebral hemorrhage. The kidneys are very large and polycystic, many of the cavities being large enough to hold 100 c.c. or more. The liver was also converted into a mass of large and small cysts. The heart was hypertrophied and the cerebral vessels were sclerotic. Microscopically we find in the kidney similar papilliferous projections covered with epithelial cells as in the previous case, but not so numerously nor so well marked, and the tissue between the cysts contains more dense homogeneous fibrous tissue and less of the renal parenchyma proper. There are foci of intense round-cell infiltration present, however. The liver was kept for some time in carbolic acid and thus rendered unfit for

[1] For Cases III, IV and V, I am indebted to Prof. Hektoen. They were studied by him, and by his kind permission his notes were used as the source from which this description of the cases was obtained.

microscopical study. It is now in the museum of Rush College, but parts have been removed. It contains cysts varying in size from that of a pea or smaller to that of an orange. A few large cysts project from the surface; in other places the surface is smooth or slightly puckered. On a cut section about one-half of the total area is occupied by cysts. Some of the large cysts are separated only by thin fibrous walls; again there may be areas of several square inches almost free from cysts. The cysts seem to be somewhat less numerous near the upper surface than elsewhere.

Case V.—Man, colored, aged fifty-seven years, who had syphilis in 1856, died July 25, 1893, with heart hypertrophy, edema and ascites, large double inguinal and umbilical herniæ. The urine was albuminous, of low specific gravity, and contained granular and hyaline casts. He traced his illness back for five months and said that it commenced with pain in the abdomen and edema of the face and legs. The post mortem was made by Dr. Hessert; there was edema, ascites, hydrothorax, and the herniæ mentioned. The heart weighed 480 grams; there was some sclerosis in the coronaries and in the aortic and mitral valves, but there was no valvular deformity. The conjoint weight of the kidneys is 2,320 gms.; the measurements, 20 x 9.5 x 9 cm. The surface is thickly studded with cysts of varying sizes, some of which have translucent, others dark-colored contents. On the cut surface all parts of both kidneys are cystic, the largest cysts being perhaps the size of a hen's egg. In some of the cysts is a dark, granular sediment. Both pelves seem normal. The ureters are patent. The miscroscopic sections from this case show that there are papillary outgrowths into cysts covered with short cells and also masses of cells pushing into the cyst-wall, but the changes are not so marked as in Case III, while the increase in the connective tissue in the parenchyma is very marked and the round-cell infiltration very pronounced.

Case VI.—Dr. Bassoe has furnished me with notes concerning a case which he observed in the Cook County Hospital while an interne in the service of Dr. Arthur R. Edwards. The patient, an Irish laborer, forty-four years old, was admitted to the hospital on July 13, 1897. He died two days after admission, during an attack of epileptiform convulsions.

Personal History.—No venereal diseases; excessive use of alcohol; smoked and chewed tobacco. The patient sought admission to the hospital on account of difficulty in breathing, which commenced one week before admission; no other symptoms except some substernal soreness.

Physical Examination.—The patient is mentally dull. The tongue is parched, rough, and coated brown. The breath is foul. The veins of the forehead are distended. The nares are dilated. The pulse is full, slow, and regular. Breathing is labored, expiration accompanied by wheezing sounds. The arteries are sclerosed. The chest is somewhat barrel-shaped, moves as a whole, and the accessory muscles are in play; the supra- and infraclavicular fossæ are filled, and the lower intercostal spaces are retracted in inspiration. The lungs are hyperresonant, fremitus is diminished, breath sounds are harsh, expiration prolonged and accompanied by sibilant and whistling râles. The area of dulness over the heart is almost obliterated; heart sounds are distinct and apparently clear. The abdomen is slightly tympanitic; no areas of dulness or tenderness. The upper border of the liver is at the seventh rib in the mammary line, the lower border two finger-breadths below the costal arch. The spleen is not palpable. There is a small umbilical hernia. A scar exists as evidence of an old lesion of the upper third of the left tibia. There is slight edema of the lower extremities. Lymphatic glands and genitalia are negative. The skin is dry and harsh; there is a bruised area over the left hip. The urine is of a light straw color, reaction alkaline, specific gravity 1.010, contains a trace of albumin, no sugar. Autopsy was held by Dr. Cook. The anatomic diagnosis was as follows:

Pulmonary edema with emphysema; adhesive pleuritis (slight); cardiac hypertrophy and dilatation; cystic degeneration of kidneys; calcification of peribronchial glands; double hydrothorax.

The autopsy record contains the following description of the organs:

The abdominal cavity contains a small amount of clear fluid; the peritoneum shows no changes. The pleural cavities contain considerable quantities of a clear reddish-yellow fluid, without any flocculi. The right pleural cavity is partly obliterated by old adhesions; the apex is free. The anterior borders of the lungs approach each other and almost obliterate the precordial space.

The pericardium is smooth; the pericardial cavity contains a small amount of clear fluid.

The mucous membrane of the larynx and trachea is smooth and is covered with a small amount of mucus. The right lung weighs 1,000 gms., the left 1,020 gms. The surface of the left lung is smooth and of a grayish-red color; its anterior edges are emphysematous; it crepitates throughout. The cut section has a uniform dark-red color in the lower portions, light, almost scarlet, in the upper portions. A large amount of frothy reddish fluid can be expressed. The right lung shows a few old adhesions over the anteromedian aspect; on the posterolateral surface, in the lower lobe, is a calcareous nodule of the size of a filbert, just beneath the pleura. Otherwise this lung is like the left. The apices of both are negative. The peribronchial glands are calcareous and pigmented. The heart weighs 410 gms., and is a little larger than the owner's fist. The left ventricle is 0 cm. long and its wall is 1½ to 1¾ cm. thick. The right ventricle is 11 cm. long

and its wall 5 mm. thick. The valves show no changes. The left ventricle contains a goose-fat clot. The mitral orifice readily admits four, the tricuspid eight fingertips. The myocardium is fairly firm and of a uniform reddish brown color.

The aorta shows a few calcareous plaques about the coronary orifices and in the arch.

The spleen measures 15 x 10.5 x 2 cm. and is rather soft.

The right kidney weighs 630 gms. and measures 16.5 x 10 x 5 cm., the left weighs 610 gms. and measures 17 x 9 x 5 cm. The surface of both kidneys is rough and is the seat of numerous cysts ranging in size from that of a pin-head to that of a filbert. One cyst of the size of a small hickorynut contains a puriform material, the others contain a clear fluid. The cut sections show both kidneys to be honeycombed with cysts; there is no distinction between cortex and medulla; there is no evidence of pyelitis. The ureters are negative, likewise the bladder.

The liver weighs 1,950 gms. Its measurements are 28 x 22 x 20 x 6.5 cm. It has a smooth surface and cut sections present a uniform brownish red color; the lobular markings are indistinct. The gall-bladder contains dark bile and no calculi.

The stomach shows no changes.

The appendix is 4.5 ins. long and lies posterior to the colon, ascending to within 1.5 ins. of the liver.

No further records of this case are available. The only symptom pointing to uremia in this case was the dyspnea. This again calls our attention to the difficulty of diagnosing cystic kidney clinically. In attempting to make a diagnosis the following points have been emphasized by various writers as requiring chief consideration. (For fuller references see articles by Hektoen and Dunger). (1) The presence of a solid or slightly fluctuating, perhaps nodular, tumor in the region of one or both of the kidneys. There may also be prominences on the liver border. If the tumor has existed for many years and there is no history of previous inflammations it is very suggestive, especially if the tumor is bilateral. Malignant growths, inflammatory swellings and other more or less solid tumors must be excluded. Deformity of the abdomen, consisting chiefly in an increase in the anteroposterior diameter of the hypochondriac region (Dunger), may be included under this heading. (2) The clinical course. This may be one of chronic nephritis extending over years, as in our first case. Decrease in the elimination of urea is not always found; there may be blood, pus and albumin. Uremic symptoms may exist for some time, or coma and death may come on suddenly as in many of our cases. Cardiovascular changes and death from cerebral apoplexy are frequent. Intercurrent affections may end life before any definite symptoms of kidney disease have developed. (3) Aspiration of fluid contents of the kidney tumor and the finding of certain minute laminated or rosette-like bodies of yellowish color and colloid consistency. These may also appear in the urine. Their presence is considered pathognomonic (Dunger), but they have not been found in all cases and even when they are present repeated aspirations and urinary examinations may fail to reveal them. (4) Family history. This has already been dwelt on. If, in our first case, an autopsy had been performed on the body of the sister who died some years earlier with similar symptoms, and the autopsy had discovered the presence of cystic kidneys, the hereditary character of the condition might have led to a probable diagnosis of cystic kidney in the surviving sister.

Case VII.[1]—J. S., an apparently young man, was admitted comatose to the Cook County Hospital in February, 1905, and died on the day after admission. No history was obtained. A specimen of urine contained sugar and di-acetic acid. Autopsy was held by Dr. Hall, and the anatomic diagnosis was as follows: Parenchymatous nephritis of the left kidney; congenital cystic right kidney; tumor of the head of the pancreas; healed tuberculosis of the upper lobe of the left lung; healed tubercles in the spleen; atheroma of the aorta; sclerosis of the mitral leaflets; edema of the lower lobes of both lungs. The small tumor of the pancreas is found microscopically to consist of minute fibroid and encapsulated caseous tubercles and parenchymatous tissue in a state of degeneration. The left kidney weighs 200 gms.; its cortex is pale and the glomeruli indistinct; there is a small amount of fat in the pelvis. Microscopically this kidney shows marked parenchymatous degeneration.

The right kidney is small; it measures 7.5 x 5 x 2.5 cm. and weighs 52 gms. The normal markings are absent. The interior consists chiefly of cysts, about thirty in number, varying in size from that of a pea to that of a walnut, and separated by thin walls; many of these cavities communicate with the pelvis, which is large and rounded. There appears to be scarcely any renal tissue proper between the cysts. The cortex is reduced to a mere shell from one to four mms. in thickness. The ureter is patent, but very narrow; the blood-vessels are very small. Microscopically the cyst-walls and the small amount of intercystic tissue are found to be of a fibrous character. In the thin cortex are a great number of glomeruli, nearly all of which are reduced to fibrous, often hyaline spots; those not so altered have thick, fibrous capsules. The rest of the cortex consists chiefly of fibrous tissue, in which we find a few atrophic tubules which are generally very small and distorted. The proliferation of tubular epithelium, which was so marked a feature in most of the other cases which have been described, is almost absent in this case. However, here and there may be seen

[1] The material for the study of this case was obtained through the kindness of Dr. Hall, Resident Pathologist of the Cook County Hospital.

a tubule somewhat wider than normal, of irregular contour, and with deeply staining cells, which may fill the lumen. The microscope reveals no cysts, in the sections studied, that were not plainly visible to the naked eye, with a single exception, viz., a round, encapsulated space two or three times as large as an average glomerulus. The interior of this space is almost filled with slender papillary processes carrying large, deeply stained cells. With this exception there is nothing that suggests a progressive formation of cysts going on at the time of death. Some diffuse round-cell infiltration is present.

It will be seen that the cystic kidney in this case presents in some respects a contrast to those previously described; it is small, unilateral, and the proliferation of tubular epithelium, which we regarded as an important factor in the cyst-formation in the other cases, is here almost absent. Whether the degenerative processes were originally the same and were later followed by cirrhotic contraction and cessation of active cyst-formation, or we have here to deal with processes of a different nature, perhaps inflammatory or developmental, is a question not easily answered.

In conclusion, I wish hereby to acknowledge my indebtedness to Dr. P. Bassoe for his kindly help and advice in the preparation of this report.

ADDRESS.

ON ASCENDING CURRENTS IN MUCOUS CANALS AND GLAND DUCTS AND THEIR INFLUENCE ON INFECTION: A STUDY IN SURGICAL PATHOLOGY.[1] [2]

BY C. J. BOND, F.R.C.S.,

HONORARY SURGEON, LEICESTER INFIRMARY.

Mr. President, Ladies, and Gentlemen.—I propose, in using the opportunity now afforded me, to depart somewhat from usual custom, and instead of attempting a retrospect of recent surgical triumphs, and of advances in surgical technic, I would rather try to throw the searchlight of inquiry in the other direction, and indicate some of the ways in which these surgical triumphs may themselves throw light upon physiological and pathological problems, and in this way enable surgery in some slight degree to repay something of the debt she owes to these two foundations of her existence.

For when we come to consider the enormous number of what are really human physiological and pathological experiments, which are performed daily for necessary and well-defined surgical objects and to save life; when we reflect on the great opportunities which the continuous observation of these operation cases affords of looking into the inner processes of bodily function, both healthy and diseased, we are bound to inquire whether we, as surgeons, have in this respect carefully observed all that we might have done, and whether we have utilized to the utmost our many opportunities.

Thus, to come closely to the matter of my remarks to-day:

The Large Intestine.—Consider for a moment the very frequent, nay the daily establishment, of fistula for surgical purposes.

The operations of colotomy, cholecystotomy, nephrotomy, cystotomy, with the resulting fistulous openings into bowel, gall-bladder, kidney, and urinary bladder, should enable us, if rightly studied, to observe something of what goes on in the hollow viscera, the biliary canals, and the urinary tract, when the fecal stream or the biliary or urinary flow is wholly or partially diverted from its normal course.

We will consider the fistulous opening in the bowel, established by the operation of colotomy, first. I have in several of these cases tried to ascertain what occurs in the bowel below the colotomy opening by means of the introduction of some insoluble, innocuous pigment, such as hollow suppositories, containing a few grains of sterilized indigo or carmine, and will record the results in several cases.

Case I.—Cancer of the sigmoid colon with obstruction. About six inches of the bowel was removed with the growth, and partial end-to-end anastomosis performed; but, owing to the patient's condition from obstruction, a colotomy anus was also established. A week later, after recovery, a carmine suppository was introduced into the rectum. A white gauze plug inserted into the lower colotomy opening showed distinct carmine coloration within twenty-four hours, and this color continued to be noticeable for several days after the suppositories were discontinued.

Case II.—The second case was one of advanced cancer, with almost complete obstruction high up in the rectum. Here again, after inguinal colotomy, an indigo suppository placed within the rectum was followed by the appearance of indigo at the colotomy lower opening within twenty-four hours. Here the indigo had passed through the malignant stricture.

Case III.—Inguinal colotomy for cancer of the rectum, with ulceration into the vagina. A suppository containing powdered sterilized litmus was introduced into the rectum on Nov. 28, at 8 P.M. The bowels were moved through the upper colotomy, opening on Nov. 29 and 30, and on the 30th the white gauze plug in the lower colotomy opening was stained blue; the blue color turned red on the addition of acid, thus showing not only that the litmus had traversed the sigmoid flexure, through the stricture, from the rectum, but also demonstrating that the intestinal mucus, and the secretion of the large intestine is alkaline in the absence of fecal matter.

Case IV.—This case is of peculiar interest. An operation for acute appendicitis with abscess, six months

1 Abstract of Address in Surgery, delivered at the seventy-third annual meeting of the British Medical Association, July 24, 25 and 26, 1905.

2 Courtesy of British Medical Journal.

previously, had resulted in a fistulous opening into the cecum, which discharged a very little feces in the right iliac region when the patient assumed the upright position. While recumbent practically the whole of the feces was passed per anum. Before closing the fistula indigo suppositories were administered twice daily on Dec. 12, 13 and 14. Distinct evidence of indigo from the cecal fistula appeared on Dec. 15, the bowels having been moved freely on Dec. 13, 14 and 15, and an aperient taken by the mouth on Dec. 12 and 14. In this case the particles of indigo traversed the whole length of the large intestine within at most three days, and during the time that the natural downward passage of fecal matter was going on, and in spite of the active clearing of the bowel on two occasions by aperients.

From these cases we learn:

First, that in the large intestine, in cases in which the fecal stream has been diverted by a previous colotomy, there is an upward current capable of carrying foreign particles such as powdered indigo along the bowel, and taking about twenty-four hours to pass from the anus through the sigmoid flexure to the colotomy opening. The shortest time recorded has been twelve hours.

Secondly, that this current is not arrested by the presence of a stricture in the rectum, provided that there is, of course, some patency of channel left.

Thirdly, from the case of the girl with the cecal fistula, we learn that it is not essential for this upward current that the fecal current should be wholly diverted or absent, or that the bowel should be prevented from undergoing brisk downward peristalsis, the effect of an aperient.

Fourthly, from the same case, we learn that this ascending current takes about three days to pass from the anus along the whole length of the large intestine to the cecum.

In offering any explanation as to the means by which this upward carriage of pigment particles is brought about we must remember:

1. That in the case of the indigo, at any rate, the particles are insoluble in the intestinal juices. Indigo, administered by the mouth, is recovered, unchanged, as far as microscopic appearance goes, from the feces, so that the material is conveyed in particulate masses, probably by a mucous stream, and not by the agency of phagocytes or wandering cells.

2. Also the current is absent in the dead bowel, and is not due to capillary flow in a closed tube. If, for instance, indigo is inserted into the lower end of a portion of sheep's colon, removed after death, no ascent of the powder occurs in the tube.

3. Further, even in healthy animals, in the absence of any fistulous opening there is some upward flow, though slight, along the bowel. Indigo, inserted into the rectum of a guinea-pig, may be found when the animal is killed, forty-eight hours later, in the feces higher up the colon.

4. Also, the current is quickened by any influence, such as the administration of an aperient, which acts by increasing peristalsis, or, very possibly, by increasing the secretion of mucus. This was shown in the last case.

In fact, a consideration of the facts strongly suggests the explanation that particles of indigo, etc., are carried up the bowel by a mucus current, and that, while there is a central downward current of solid or semi-solid feces, caused by peristaltic contraction, there is going on at the same time, intermittently, or possibly alternating with the downward peristalsis, an upward peripheral mucus stream, covering and hugging the intestinal mucous membrane, and capable of conveying minute particles only along with it.

Some sort of upward intestinal current has been suspected in the large bowel, and hypothetically spoken of as due to reversal of the peristaltic wave. This is an unlikely explanation from the facts mentioned above—that it is present while the downward peristalsis is going on at its normal rate, and also when the bowel is quite empty of any feces at all.

I venture to think that these facts have a not unimportant bearing on the physiology of a large intestine. By means of such an upward stream the nutritious fluids and particles which are being absorbed out of, or squeezed out of, the gradually solidifying and hardening feces, as they traverse the colon, are carried gently upwards into the emptying upper reaches of the bowel, and are presented to the free mucous membrane for readier absorption. They, too, have a direct bearing on therapeutics and on the administration of enemata, both nutritive and purgative.

The Female Generative Tract.—We now pass to the consideration of the female generative canal. Here surgical operations on the Fallopian tubes have afforded opportunities for careful observation.

In a considerable number of cases during the last two years in which it appeared likely that operation would become necessary on the appendages, after the preliminary douche a little colored pigment—in most cases purified and sterilized indigo, in a few carmine—has been either placed upon or inserted just within the os uteri at varying periods up to twenty hours before operation. Careful microscopical examination of the contents of the Fallopian tubes in these cases has nearly always shown the presence of indigo or carmine particles, while in several cases the pigment has been found on the peritoneal surfaces of the broad ligament, mesosalpinx, and the fimbriæ of the Fallopian tubes. This shows that the particles are carried from the os uteri below, right through the uterus and the Fallopian tubes, to the peritoneal sac around the ovary above.

In the case of these pigment particles, automobility (such as the spermatozoa possess) is of course out of the question, and we must fall back on ciliary action, or an ascending mucous stream along the contiguous walls of the mucous canal.

Before, however, we enter on any explanation, it will be well to analyze the results more fully.

Thus in 22 cases in which careful examination was made of the contents of the Fallopian tubes and peritoneum for the presence of indigo introduced into the os uteri at periods up to within twenty hours before operation, there were only four in which no pigment was found.

Of these four cases one was a case of double hydrosalpinx, in which any connection with the uterine cavity was difficult or obliterated.

In one the indigo had been inserted only sixteen hours before operation.

In two cases the indigo was inserted on the first day of the establishment of the menstrual flow, and probably failed to enter the uterus.

On the other hand, positive results were obtained in three cases of double pyosalpinx. In one case of uterine fibroid and in two cases of tubal pregnancy in which rupture or tubal abortion had occurred. One of these is interesting from the fact that the remaining left ovary and tube had been removed two

years previously. The indigo was found in the bloody mucus contents of the tube on the uterine side of the rupture and in the blood filling the conception cavity.

Indigo was also found in two cases of chronic appendage disease, in which the indigo was inserted on the last day of the menstrual period, and in two cases of hysterectomy, which are of special interest. In one the patient was seventy years old, and therefore the uterus was senile. In the other the uterus was removed some months after the artificial menopause produced by oöphorectomy twelve months before. These two cases clearly show that this upward mucous stream is not dependent on the functional activity of the uterus, since it occurs in the senile and post-climateric organ as well as in the actively functional state.

In two cases of large ovarian cysts pigment granules were found on the peritoneum, and in the contents of the tube dilated and stretched over the cyst wall.

In the case of suppurating ovarian cyst with pyosalpinx indigo was found in the pus in the tube. It was also found in three cases of chronic inflammatary disease of the appendages; probably gonorrheal in origin.

In one case of large pyosalpinx and ovarian abscess on one side and hemosalpinx on the other, operation became necessary while the temperature was 104° F., and twenty-eight hours before operation pus began to escape from the uterus. Indigo was found in the bloody contents of the left tube, but not in the pus in the right tube, or that of the ovarian abscess. No doubt the particles were washed away from the uterine opening of the right tube by the flow of matter from the opening.

I desire also to draw attention to the presence of the indigo within the pus cells in one of the two cases of pyosalpinx. The granules were actually ingested by the cells, and lay scattered as blue pigment grains in their interior. In fact, we had succeeded in feeding the pus cells with indigo, and had produced an intravitam staining.

Two explanations are possible: Either the material had entered the blood, or lymph stream, and had been ingested by leucocytes or phagocytes, which had then migrated into the abscess, or the pus cells had ingested the granules *in situ* in the abscess, after the pigment had been carried thither up the Fallopian tube. This will, I believe, prove to be the true explanation, and also carries with it the interesting fact that pus cells, as such, after their entry into an abscess are capable of ingesting foreign particles into their interior.

In the other three cases of double pyosalpinx examined indigo was found in the pus in the tubes, but not in the cells. Now, in these cases there was no manifest discharge of matter from the uterus, though the presence of the indigo in the tubes proves that the communication between the tubes and the uterus was still patent. In fact, I believe that this is the case in most, if not all, cases of pyosalpinx. Blocking, temporary and intermittent, no doubt occurs of the lumen of the tube on the uterine side, but bearing in mind how difficult it is, even by operation, to obliterate the channel by any means, short of excision. I think it very probable that some communication exists in most of these cases of secondary infection of tubes with purulent contents, and that an occasional slight escape of pus occurs, with corresponding relief of intra tubal tension.

In fact, the whole subject of tubal regurgitation of uterine contents is very interesting. We know from the artificial production of hydrometra and hydrosalpinx in animals, under aseptic conditions, that regurgitation of the hydrometric fluid from the distended uterus is much prevented by the sudden deviation of direction which the tube takes in passing through the uterine muscular wall. At the same time, no opposition is encountered by the mobile spermatozoa in their upward passage. As we also now know, from the observations I have just described, that foreign particles of a suitable size, if introduced into the vagina, are habitually carried up the whole length of the genital canal in women. It is not absolutely necessary that the indigo should be inserted into the cervix, for, if deposited in the upper vaginal vault, it is still found occasionally in the tubes at the operation.

The question of the size of the particles is an important one. Particles up to the size of lycopodium grains are carried up, but this seems to be about the limit, as I have found lycopodium (a very few grains) in one case only.

This same upward current exists also in animals, for I have repeatedly found indigo particles in the Fallopian tubes of rabbits after insertion of the powder in the vagina.

I wish also to record an observation at this point on the question of mucus currents in the oviduct of birds. After dusting indigo on the cloacal opening, or after insertion of the powder within the cloaca in fowls, the pigment was found, not only upon, but also sparingly incorporated in, the egg-shell, and I have seen it in the Viteline membrane, thus showing that it had passed up the oviduct. Further observations are necessary to ascertain whether this occurs only at certain periods or throughout the egg-laying period.

I feel sure, however, from repeated observations during intra-abdominal inspection of the fimbriated ends of the Fallopian tubes during the menstrual period, that regurgitation of menstrual blood and mucus occasionally occurs from the abdominal ostium of the tubes; moreover, blood is sometimes found free in the pelvic cavity without symptoms and apart from any question of tubal pregnancy. In fact, I have no doubt that in many cases of dysmenorrhea in young women the pain is really tubal in origin, and is due to peristalsis of the tube in its effort to overcome this regurgitant wave. The pain, in fact, is due to tubal, not uterine colic.

Let us for a moment consider one other important fact, depending on the establishment of the presence of this upward, utero-tubal, mucus current. Those who are brought in contact with uterine cases know that gonorrheal and puerperal poisons, although the most important, do not exhaust all the sources of tubal and peritoneal infection.

The mere exposure of the upper vaginal tract to dirt, to lotions and ointments, to any substance surgically unclean, by whatever means introduced, has in many cases originated the salpingitis and chronic endometritis, and I am not without hope that this picture of the constant upward mucus-current which I have described may produce a greater sense of responsibility in surgeons, and tend, perhaps, to check some of the indiscriminate curetting operations which are so fashionable, and which (while the only treatment in some cases) in others only aggravate the troubles they are supposed to cure.

Fortunately the door, though open, is guarded by the watchful peritoneum. Foreign particles and fluids introduced, as it were, guttatim, by the tiny canal of

the tube, if not too virulent, are at once incarcerated and rendered inocuous. But it should surely make us all most careful to know that any powdered substance we introduce into the os uteri will probably be found, within twenty hours, inside the peritoneal cavity.

The Upper Intestinal Tract.—I shall say a few words later about the means whereby this current is brought about; meanwhile, we pass to the consideration of the upper intestinal tract and the mucous ducts of the glands opening into it.

The gall-bladder is the viscus which, owing to its frequent exploration and drainage for surgical purposes, is specially adapted for investigation on these lines.

I have examined the bile in several cases of gall-bladder fistula following the removal of gall-stones, systematically and daily, for varying periods, indigo being administered by the mouth in cachets containing about 5 gr. during the same period. The bile collected from the fistula is allowed to deposit a sediment, which is examined microscopically, and, in some cases, centrifugalized.

The indigo thus administered by the mouth makes its appearance in the feces about forty-eight hours later, and colors them a dirty or slaty-blue color, which on microscopic examination is found to be due to indigo grains in masses. This shows that most of the indigo passes unchanged, by gastric, pancreatic, or intestinal digestion, through the alimentary canal.

The following are the details for cases examined:

Cholecystotomy for gall-stones and drainage, Nov. 8. On Nov. 20—twelve days after the operation—the patient commenced taking indigo, 5 gr. twice daily for one week. Indigo was found in the bile from the fistula two days after taking the drug.

Cholecystotomy for gall-stones and drainage of gall-bladder on Dec. 1. Indigo was administered on Dec. 5, and on Dec. 7—two days later—indigo granules were found in the bile from the fistula.

Cholecystotomy for distended gall-bladder containing clear bile-free mucus, due to the impaction of a gall-stone in the cystic duct. In this case indigo was commenced four days before the operation. None, however, was found after careful search in the bile-free mucus obtained from the gall-bladder at the operation, or in the bile obtained from the fistula two days later. On Dec. 27, however—six days later—while the patient was still taking indigo, and some 6 oz. of bile and mucus were escaping daily from the fistula, indigo granules were freely found in the mucus coating the wick of white sterile gauze in the fistula, and in the bile collected in the bottle and flowing from the fistula.

Cholecystotomy.—Indigo administered four days before operation. Gall-bladder opened, inflamed; two stones were impacted in the common dilated duct. No indigo was found in scrapings of the gall-bladder mucous membrane, or in the mucus covering the gall-stones at the time of operation. Three days later, however, a few indigo grains were found in the bile flowing from the fistula, and two days later still more was found in the mucus flowing from the gall-bladder and coating the gauze wick.

These cases, then, suggest the fact that a reflux mucus stream becomes established from the duodenal papilla, along the bile ducts to the gall-bladder, in cases in which a fistulous opening has been made into the gall-bladder and by means of this current the indigo particles are conveyed.

It will no doubt be urged, on the other hand, that the indigo was absorbed in the ordinary way, by blood or lymph stream, from the gastric or intestinal mucous membrane, and was only detected in the bile after excretion by the liver. There are, however, many facts which oppose this explanation.

We have seen that indigo passes, for the most part, unchanged through the alimentary canal, and is not absorbed from the stomach or intestine. It is, of course, known that soluble indigo, in the form of sulphindigotate of soda and other soluble dyes, such as carmine solutions administered by the mouth, do color the bile (see Naunyn on Cholelithiasis. New Sydenham Society).

I find on examination that indigo, itself a very insoluble substance, is slightly soluble in bile, and can be deposited from such solution on evaporation as minute crystalline needles, and never, as far as my observation goes, in the shape of large or amorphous particles. Now the indigo obtained from the fistula in these cases was in the form of fair-sized, irregular masses, sometimes bright blue granules, never crystals. Moreover, it is a suggestive fact that they are found chiefly in the mucus lining the gall-bladder, rather than in the rapidly flowing bile.

Further, in the third and fifth cases indigo was absent from the contents of the gall-bladder and bile duct at the time of operation, although the patient had been taking it previously, while it was found in the bile and mucus regurgitating from the fistula when this was fully established some days later.

In order to throw additional light on this point, I fed a guinea-pig for some days with indigo, and then, after killing the animal, examined the contents of the gall-bladder. No indigo was found in the bile contained in the gall-bladder, nor did any crystallize out on evaporating this dryness. A scraping was then taken of the mucous membrane lining the gall-bladder, and numerous bright blue indigo granules were found. The bladder itself was then opened out on a slide and cleared, but no indigo was found in the peritoneal or muscular coats. This observation is also important, as in this animal the bile and gall-bladder currents were normal, and unaffected by fistula.

On these and other grounds I have no doubt that the indigo found in the bile in these cases is actually conveyed along the mucous channel of the bile and cystic duct from the duodenum, and not by way of the blood or lymph stream. No doubt it is only sparingly present, and considerable examination of quantities of bile and mucus is necessary to find it. But we must remember that the opening of the biliary papilla in the duodenum is only a lateral one—an open window, as it were, past which, and not directly into which, the hurrying duodenal stream of semi-digested food is passing, and it is only such few particles of indigo as adhere and cling round the opening of the duct that will be carried by the mucous current along the duct to the gall-bladder.

It will be suggested that if indigo particles find their way thus, why not particles of food? And, indeed, I think it very probable that such small particles do pass in this manner from the bowel under the altered conditions of the bile circulation, in fistulæ of the gall-bladder. I have myself found, in the fistulous bile, along with blood, cells, bile pigment, epithelial cells, pus and other substances—particles which look, under the microscope, suspiciously like cellulose and vegetable fiber.

We must remember that, owing to the surgical operation, and the establishment of the gall-bladder

fistula, the normal action of this viscus has been suspended, there is no longer any outflowing stream of mucus passing from the gall-bladder along the cystic and common bile ducts into the duodenum. In fact, there are many difficulties in accepting the conventional, bile reservoir, function of the gall-bladder. And in view of the demonstrated importance of a continuous mucous stream, along the bile, and other mucous ducts, in the direction of their flow, I am strongly inclined to think that one important, if not the chief function of the gall-bladder, is to supply this lubricating stream.

The question of the origin of gall-stones also intrudes itself on our notice. Does the demonstrated passage of inorganic particles along the bile ducts from the bowel, under the abnormal conditions of gall-bladder fistula, throw any light on this important question?

I fear at present we are not justified in making any definite statement on this point. Given, however, a temporary cessation of normal bile flow along the ducts, or of a normal mucous flow from the gall-bladder—a condition, in fact, produced pathologically, somewhat resembling the condition present in gall-bladder fistula, produced by surgical operation—we may, I think, say this much: that it is probable that not only may the upward passage of even non-motile infective organisms be possible, but that minute foreign particles may, under these conditions, find their way into the gall-bladder and serve as nuclei for the deposition of biliary concretions.

We know from Naunyn's valuable work on cholelithiasis (see New Sydenham Society's *Translations*, 1896) that pathological changes in the epithelium lining the biliary passages are more important factors in the causation of gall-stones than any alteration of the chemical composition of the bile. Naunyn also showed the influence of stagnation of bile in this matter and the important rôle played by pyogenic organisms derived from the intestine, especially bacillus coli, in causing the cholangitis and catarrh of the mucous membrane of the ducts.

We know from the observations I have described that the temporary diversion, or reversal of the direction of, the bile current brought about by gall-bladder fistula favors the entrance of minute particles from the duodenum into the bile ducts. Does it not, therefore, appear likely that the temporary stagnation of bile flow, probably associated with cholelithiasis, and present in certain pathological conditions of the liver and duodenum, may really operate by bringing about a like entrance of micro-organisms along the common duct, with possibly, minute foreign particles also, which may serve as condensation nuclei. Is it not probable that many cases of so-called catarrhal jaundice are thus explained?

The Urinary Tract.—We now pass to the consideration of the urinary tract, from the kidney to the bladder, and from the bladder to the surface by way of the male and female urethra.

We will consider the ureters first. Reverse infection of the pelvis of the kidney so frequently occurs from interference with bladder function by septic instrumentation that the ureter is universally regarded as the usual channel of infection, and not the blood stream. When we come, however, to consider the manner of this ureteral infection, the successive steps are not so clearly known.

In extreme cases of marked obstruction to the outflow of urine from the bladder, in which backward pressure of urine leads to dilatation of the ureters, and in which the interior of the bladder has become infected, by instrumentation or otherwise, it is of course quite possible that the open water-way, by arrest or reversal of current, may explain the upward carriage of infective organisms. At present I have not had an opportunity of testing the transference of indigo to the pelvis of the kidney in these cases. The more important point, however, was, if possible, to determine whether, supposing that from any cause (such as the establishment of a renal fistula) the normal downward current of secretion from the kidney to have been arrested—whether under these circumstances any regurgitation of mucous stream occurs in the normal, or at all events undilated and competent, ureter.

The following case has an important bearing on this point:

Lumbar Nephrectomy for Cystic Destruction of the Kidney by Calculus Impacted in the Lower End of the Ureter.—The calculus was detected by a probe in the ureter at the time of the nephrectomy, but the condition of the patient was such that it was thought wiser to bring the open end of the ureter to the skin surface in the loin, and remove the calculus at a later date through a vaginal incision. This was done one week later, and a good recovery ensued. After the operation of nephrectomy the bladder was irrigated daily, and two drachms of an iodoform emulsion, containing sterilized indigo, allowed to remain in the bladder.

The fistulous opening of the ureter on the loin was lightly plugged with a little white sterile gauze. This and the muco-pus from the ureter were examined daily, and on three occasions numerous indigo particles were found, showing that here, at all events, a reverse mucous current had passed up the ureter in the absence of any urine.

The position, then, at present, is probably this: Given an arrest, from any cause, of the normal downward current of urine along the ureter it is possible that a backward mucous current may occur, carrying with it any infective organisms or foreign particles, such as pus, or blood cells, or débris, which may be present in the bladder.

What we do not at present know is whether this regurgitation occurs in those cases of kidney infection in which there is no direct evidence of arrested secretion. We are not at liberty to assume, however, that even in such cases temporary arrest does not occur. It is, indeed, known that the flow of the urine from the ureteral orifices is intermittent under normal circumstances; it is possible that this intermittency may be increased to the point of temporary arrest under pathological conditions.

We still have to consider the question of the entrance of infection into the bladder from outside; the conditions, in fact, of the mucous currents in the urethra.

I will first consider the male urethra. The conveyance of infection from the exterior, in the absence of any outside interference, with a normal flow of urine along a healthy urethra is, of course, practically unknown. But, as in the case of the gall-bladder, the frequent performance of suprapubic cystotomy for surgical purposes, in the urinary bladder, affords opportunities of investigating what goes on in the urethral mucous canal.

I have investigated two cases of suprapubic cystotomy in which the bladder was drained by Sprengel's pump after prostatectomy.

Complete Prostatectomy.—Oct. 20, 1904. Bladder drained suprapubically by Sprengel's pump, blood was present in the urine for ten days, then clear. On October 31, ten days after operation, indigo was inserted within the urethra four inches from the meatus in the

eye of a Jacque's catheter, and again two days later. The urine drained suprapubically was collected daily, and the sediment examined. Indigo grains were found sparingly in the deposit.

Noticing the difficulty in finding such a minute quantity of indigo in such a large quantity of fluid, and the labor involved in searching for it, in the next case I adopted a somewhat different technic.

Prostatectomy for Adenomatous Prostate and Suprapubic Drainage of the Bladder by Sprengel's Pump.—March 25, 1905. The urine remained blood stained for one week after operation, but when clear, eight days later, a little sterilized indigo was inserted into the penile urethra just within the meatus, on one occasion only, no urine having been passed per urethram.

A small piece of white sterile gauze was placed at the bottom of the suprapubic tube or silver cannula, and this served as a filter, through which the urine and vesical mucus passed, before being drawn out by the aspiration of the small inner glass tube, through the suprapubic opening.

The gauze was removed about twenty-four hours later, and a cover-glass preparation taken of the mucus and urine which it contained. Bright blue indigo granules were freely found in varying sized particles.

Now, since all source of accidental contamination from outside was avoided by a dressing over the suprapubic opening, the indigo can only have gained access to the interior of the bladder by traversing the urethral canal.

Further, we must remember that in both these cases no instruments had been passed, and that the urethra was uninjured, at any rate up to the triangular ligament and prostate portion. The main point, of course, being that all passage of urine had been arrested for some days along the mucous canal.

I have also tried inserting indigo within the urethra alongside of a catheter retained in the urethra and bladder, in cases where it has been necessary for surgical reasons for some days to drain the bladder through a tied-in catheter. In several of these cases I have recovered the indigo from the urine flowing from the catheter, showing that the material has passed centripetally along the urethra to the bladder. I do not feel, however, that much stress can be laid on this, as there is always more or less to and fro, or inward or outward movement of any instrument tied in the bladder: it tends to be expelled, and is passed back again and re-secured, as the movements of the patient after its position, and it is thus quite possible that, by friction of the instrument against the wall of the urethra, any material might be mechanically conveyed, in successive waves, along the urethra to the bladder.

This objection does not, of course, apply to the previous cases in which no instrument was used; but, at any rate, the experience of the latter case shows how easy it is for infection to be conveyed from a dirty meatus alongside a retained instrument into the bladder; for if inorganic particles can float, as it were, in the mucous stream which is set up between the instrument and the urethral wall, and are carried thus backwards into the bladder, infective organs can do the same. It is not necessary to assume that they must be conveyed on the point of or by a dirty instrument; they may reach the bladder by way of the urethra from the surface at the meatus after the introduction of the instrument.

In fact, surgeons know well that even though the urine be received by a tube direct from the catheter into some antiseptic fluid, without contact with the air, yet it is practically impossible to keep the bladder aseptic for any length of time in cases in which an instrument traversing the urethra is tied in the bladder, and I think the above observations throw some light on the manner in which, and the route by which, this infection is brought about. At any rate, they point to the extreme importance of guarding the external orifices, and probably careful disinfection of the external meatus and the application of efficient antiseptic filtering dressings at this spot would have a good influence in preventing bladder infection in the manner above described, especially in those cases (and they should be very few) in which it is necessary to tie an instrument in the bladder.

One word as regards the short female urethra. In one case of vesico-vaginal fistula, with a very considerable opening, in which it was necessary to perform suprapubic cystotomy and operate from within the bladder, the opportunity afforded by subsequent suprapubic drainage was utilized to trace the urethral mucous stream in the female urethra. A little indigo was inserted just within the meatus, and a small filtering plug of sterile gauze inserted in the suprapubic tube through which the urine was draining. Indigo granules were found in the mucus coating this plug when removed six hours later.

We have thus traced the reflux passage of inorganic particles of a recognizable substance, like indigo, from the surface, along the urethra to the bladder and from the bladder to the upper end of the ureter. In all cases the important associated condition has been that the normal flow of urine has been diverted.

We still require observations on cases of pyelitis, made at the time of the operation, when the pelvis of the kidney is first explored, and in which indigo has previously been inserted into the bladder.

Observations on animals will probably be necessary to investigate this point, under conditions in which no previous diversion of the urinary flow has been brought about by surgical operation or disease.

The mode of infection of the epididymis by the tubercle bacillus, or by the gonococcus, or pyogenic organisms requires further examination.

I have not yet been able to test the mucous current in the vas deferens, but I think it likely that sterilized indigo inserted into the prostatic urethra in suitable cases will be recovered from tuberculous and other abscesses in the epididymis or the vesiculae seminales. If this should occur, then, the mucous canal of the vas deferens, and not the blood stream, will probably be the route taken.

Respiratory Tract.—With regard to the respiratory tract, and the mucous canals in connection with it, the accessory nasal cavities, the Eustachian tubes, and the bronchi, any observations on this part of the body are all, of course, open to the obvious objection that foreign particles may be, and no doubt are, carried by the air currents and distributed over the mucous surface.

I should, however, like to mention one case of chronic otitis media, with tympanic perforation, in which sterilized indigo was insufflated for four days into the retropharyngeal cavity. The muco-pus flowing from the external meatus was collected on both sides, and on the fourth day showed abundant indigo granules.

Of course, it will be objected that owing to some effort of sneezing or blowing of the nose the material was transported up the canals by a blast of air. The patient was instructed to avoid all such expiratory efforts, and I am inclined to think that the presence of the indigo in the internal ear is not due to this cause.

Supposing, however, that such is the case, it is surely a matter of considerable importance that in, at any rate, cases of perforated drums, not only air currents should pass habitually from pharynx to middle ear, but that

foreign particles should also find their way up the Eustachian tubes in the absence, of course, of all instrumentation. The bearing of this on the question of conveyance of infection from pharynx to middle ear is obvious, though, in the case of tympanic perforation, the important condition of diverted flow is present.

Glands.—We now pass to the consideration of the glands with ducts opening on to the surface of the body, and the possible conveyance of pigment particles along the ducts, from the skin to the alveoli of the glands.

The mammary gland, with its numerous ducts opening on the nipple, is the largest and most important of these glands. In a case of duct cancer of the breast, for six days before removal of the breast sterilized indigo was rubbed on the nipple twice daily, and a simple dressing of wool worn. Great care must, of course, be taken to avoid contamination of the exposed breast tissues at the time of the operation, but this, after all, is an object lesson in surgical technic, and the same precautions in the way of repeated washing and sterilization of the skin, which are taken to prevent contamination by skin organisms, will apply to the indigo also. In order to ensure absence of contamination, I have either coated the nipple and surrounding skin to be excised with a layer of gauze and collodion, or, having turned up the flap of skin to be excised inwards all round the nipple, I have tied this by a purse-string suture, thus leaving only the raw surfaces exposed.

The whole breast, after removal, is laid on a slab, with the deep surface uppermost, and the incisions are made into the breast tissue in the neighborhood of the ducts and into the portion affected by the cancer. Scrapings were taken from these incisions and indigo granules were found sparingly, but from several parts of the breast. Other cases of mammary cancer have yielded the same result. I have also examined unstained sections of breast tissue obtained in the same way in two cases of cystic disease associated with chronic mastitis, in which indigo had previously been applied to the nipple, and detected it in the breast.

In a case of chronic mastitis, with a scirrhous nodule in one part of the breast, in which indigo was applied for four days before operation, the pigment was found in the portion of mammary tissue containing the ducts, just beneath the nipple, but not in the solid portion invaded by growth. Now, the importance of this fact, of the conveyance of pigment particles from the skin to the deeper parts of the mammary gland, along the lacteal ducts, lies in its application to the question of the transference of infective organisms by the same route.

Here, again, it is a question of conveyance by blood, or lymph stream, as against the transference by mucous currents along the ducts, and it seems to me that the demonstration of the passage of inorganic pigment particles by this latter route strongly confirms the suspicion that it is by these duct channels that pyogenic and probably tubercular organisms gain access to the mammary gland.

I feel some hesitation, in the present unsettled state of the cancer problem, in mentioning cancer in this connection. All I will permit myself to say is this: That, if in the course of future research, the exciting cause of cancer shall be proved to be parasitic, the above observations may stimulate inquiry into the nipple route, as a possible channel of infection in cancer of the breast.

Conclusions.—We have now passed in review the conditions present in the more important mucous canals and gland ducts opening in the interior of the body, and in one case in the ducts of a gland opening on the skin surface, and a few general observations bearing on the facts so observed may not be out of place.

I think from the observations I have described we may consider it proved that by some means or other, and under certain conditions, particles of an insoluble substance, such as indigo, inserted into the orifices of a mucous canal or duct are conveyed along the mucous channel in a reverse direction to that taken by the contents of the tube, or by the secretion or excretion of the glands along such ducts. The conditions which seem to favor this passage are:

First, some interference with the normal flow of the contents of the mucous tube or duct; some arrest or diversion of secretion, such as is produced by a fistulous opening, though it is by no means necessary that this should be complete.

By what agency is this transference of foreign particles brought about?

Ciliary Action.—Though present in the upper generative tract, cilia are absent in the lower genital tract, in the intestinal canal, in the biliary ducts, in the urinary tract, and in the ducts or glands opening on the skin.

Muscular Contraction.—No doubt irregular or reversed peristaltic contractions in the bowel, if present, would bring about the result. It is, however, suggestive that the ascent of the indigo up the colon is not prevented, but rather accelerated, by the increased downward peristalis produced by purgatives. Reverse muscular contractions are as yet, moreover, unknown, or rather undemonstrated in the bile ducts, urethra, and urinary tubes, Fallopian tubes, or in the ducts of glands.

The phenomenon is not due to physical agency alone, such as capillary action. It is absent in the non-living tube. The transference of particles in empty tubes and ducts is one, and there are other reasons, before explained, for regarding the mucus which coats the walls of the tube or duct, as the vehicle in which the particles are carried. Further observations are necessary to ascertain whether a reverse current—a sort of mucous backwater—is present in all mucous channels, or whether it only exists where the normal outgoing current of secretion or excretion is interfered with. Such a back current is probably present to a certain extent normally, though much increased by any agency, such as a fistula, which starts a flow of mucus from the other end of the canal.

The essential conditions, then, seem to be a living tube, whose walls are partially if not wholly in apposition, and lined by a mucous secretion; while the reversal of this mucous current is favored by any condition (such as a fistula) which leads to arrest or diversion of the ordinary secretion of the viscus or gland.

The bearing of these remarks on the larger question of infection will be at once apparent.

I am inclined to think that in some cases more attention should be paid to mucous channels as routes of invasion, rather than to the lymph or blood stream. Thus I have spoken of the large share which such a mucous, as opposed to a blood infection, plays in the diseases of the female generative tract. The rapid ascent of the urethra by the non-motile gonococcus, and the colonization of deeper portions of the tube, apart from direct extension of growth and in the absence of instrumentation or injection, are thus explained. The ascending infections of the kidney by way of the ureter can also be investigated from this point of view.

Our knowledge of the causes which produce biliary and urinary calculi is still very incomplete. The facts which point to the importance of diseased conditions

of the mucous linings of the excretory tubes, in favoring the disposition of concretions, are of especial importance from this point of view. And bearing in mind the proved transference of particles, under certain conditions, from duodenum to gall-bladder and from urethra to ureter. I hope that further light may thus be thrown on these calculous diseases.

In fact, the burden of my remarks points to the necessity for the active recognition of the importance of all communications between the efferent canals of the body and the external world, and thus accentuates the value of personal hygiene and true cleanliness.

Gentlemen, I hope I have not wearied you with these remarks on what may be called surgical physiology and pathology. As I said at first, instead of pointing to new operations or improvements in surgical technic, instead of giving statistical tables indicating case-mortality after operations, I have tried to turn your attention the other way, and to glean a few facts from the many opportunities which modern surgery affords for the observation of fundamental processes of organic life.

And yet, without the surgical revolution which we owe to a few great men, and which has been one of the glories of our century, these life-giving operations would have been unperformed, and the light which they have shed in many a dark corner of the human body would never have shown.

Though the public (the mass of our fellow-creatures) are only beginning to grasp, as yet very imperfectly, the all-pervading influence which medical and surgical science, and indeed all the sciences which deal with physical and mental efficiency, will assuredly soon exert in the life of the Individual, the City, the Nation, and the State; yet it is surely fitting that we medical men, who know these things, should ever recall the services rendered to humanity by the Pasteurs, the Listers, the Kochs, and all those who have done so much to raise our calling to its present proud position—all those who have made these things possible.

And how better can we show our gratitude to them than by strenuous individual effort, each of us, in spite of much distraction and scanty opportunity, to add one small fact to the store of garnered knowledge; to bring even one stone to the building of that glorious Temple of Health whose topmost pinnacle will only be finished when disease and suffering have been finally vanquished.

MEDICAL PROGRESS.

NEUROLOGY AND PSYCHIATRY.

The Fear of Death.—J. Leonard Corning (*Jour. A. M. A.*, May 6) discusses the morbid exaggeration of the fear of death, which he considers due to a neuropathic basis inherited or acquired. In animals the fear of death is dependent on its imminency; in man it is sometimes a permanent obsession, but it is even then usually absent in the actual process of dying, the dulling of consciousness at that time and other dominating physical conditions accounting for this fact. He reports a case illustrating what he considers the essential psychology of the morbid dread of death, in this case even exciting suicidal impulses—death to escape death. In treating this condition he would suggest the thought that sleep is a sort of death, and unconsciousness whether lasting or not, a boon. His treatment was to prevent sleep until it was sought imperatively, and was based on the theory of proving experimentally that the temporary unconsciousness of sleep is the remedy for curable shortcomings and convincing the reason that the more lasting unconsciousness of death is only the supreme antidote of the irremediable breakdown of the organism, and therefore supremely benevolent in its essential nature.

Syphilis and General Paralysis.—The following conclusions are offered by Joffroy (*La Clinique*, April, 1905): Syphilis is not the efficient cause of general paralysis, which is not a disease of syphilitic nature. Mercurial treatment is of no value in the prophylaxis of paresis, which is not cured by it, and which may be made dangerous by this treatment.

Suggestion—E. J. Runyon (*Jour. A. M. A.*, May 6), calls attention to the need of a proper mental attitude toward the power of suggestion, which, as he says, "runs like a thread through every method of treatment, wise or otherwise." He also notes the dangers of self-deception in medicine and of drawing deductions from imperfect data or without due power of discrimination. While suggestion is often a power for good in the hands of the physician, it is one that may be abused and result in great and lasting harm. It is the main instrument of the pretenders; he reviews some of the noted instances of their exploitation of human credulity. The point emphasized by him is that the true practice of medicine is the intelligent application of common-sense principles and forces.

Chronic Nephritis.—W. M. Leszynsky (*Med. Rec.*, May 20, 1905), says that, aside from the various neurasthenic manifestations occurring in patients with chronic nephritis, many of the transitory subjective nervous phenomena arising during the course of the disease are the result of uremic—or possibly other—intoxication in varying degree, while nearly all of the transitory objective nervous phenomena, and the more permanent and incapacitating or fatal complications, are primarily due to the concomitant arterial disease. Hence palpable evidence of arteriosclerosis and high blood-pressure is usually of the greatest significance. The many forms which the nervous disturbances attendant on nephritis assume are described in detail, and several illustrative cases are cited in which the failure to recognize the uremic condition underlying symptoms apparently of nervous origin led to serious results.

The Curability of Early Paresis.—C. L. Dana (*Jour. A. M. A.*, May 6), suggests that paresis, like tabes—with which it is closely related as a parasyphilitic disorder—may be arrested in its earlier stages. By "arrested" he does not mean the well-known remissions of the disease; in these, he says, there still remains a certain amount of paretic mental impairment, but he rather means a complete disappearance of all evidence of degenerative changes in the brain. He reports a number of cases illustrating his contention, in which symptoms decidedly indicative of paresis appeared, characteristic mental changes, convulsions, Argyll-Robertson pupil, etc., but which disappeared under treatment, and the patients remained well for various periods under observation. The treatment generally consisted in complete change of life, antisyphilitic medication, preferably hypodermic, hydrotherapy, and attention to the general nutrition. He says there is no *a priori* reason why paresis in the early stages may not be sometimes cured, and he holds that the cases he here reports point that way and indicate the importance of an early diagnosis and treatment of this disorder, which has been heretofore considered incurable.

Functional Insanity.—In a treatise on this subject R. Jones (*Practitioner*, May, 1905) advances the view that many of the morbid mental conditions known as insanity are functional, and that therefore there are diseases of function as well as of organs. The author states that while we are accustomed to find in disease fine structural alterations, which account for the morbid phenomena, yet nature may experiment in so fine, subtle and obscure a manner as to alter the function of an organ or group of organs, without leaving any evidence of definite or appreciable change in structure. There are many cases who suffer from perverted sensations, or anesthesias, parasthesias and dysesthesias, from pains or algesias, from loss of power or paresis, from various affections of the sense organs, and even from mental abnormalities, yet who have no discoverable nervous lesions to account for these symptoms, and whose lowered vitality and consequent incapacity can only be described as functional. In support of this view the author states that if we except definite lesions accompanying paretic and other forms of dementia, certain neuronic and other changes in acute delirium, and the deficiency of brain development in idiocy and imbecility, there is no pathology of insanity. The author includes in the class of functional insanity which have no demonstrable pathological lesions the following classes of cases: Hysteria, epilepsy, hypochondriasis, chorea, suicidal manifestations, some forms of alcoholism. Throughout this class there is always an inherited tendency toward the production of the same mental affection.

Intermittent Claudication and Allied Syndromes.—J. R. Hunt (*Med. Rec.*, May 27, 1905) contributes an exhaustive study of all aspects of this affection, which was first described by Charcot in 1858. The literature since that time is reviewed, and alcoholism, syphilis, gout, nicotinism, diabetes, exposure, flatfoot, compression by a truss aneurism the neuropathic diathesis and congenital insufficiency of the cardiovascular apparatus are cited as etiological factors. The pathological findings may be summed up in the one word, angiosclerosis, though in advanced cases secondary changes of a trophic nature frequently occur, and the vasomotor element is also of importance in producing the spasm. While the typical picture of the disease comprises intermittent limping with the paroxysm during activity and complete freedom during rest, sensory symptoms and weakness may in some cases be present more or less constantly and give rise to errors in diagnosis. Cases in which the anus, rectum or bladder, brain, kidney or retina were affected have been recorded, and it is also thought that the paroxysms of angina pectoris were referable to a similar condition of the coronary arteries. The prognosis as regards cure is unfavorable, but by suitable treatment, consisting of rest, potassium iodide, cardiac tonics, warm foot baths and galvanic foot baths, much may be done toward warding off indefinitely the threatened gangrene. Digitalis, ergot, nitroglycerin, very hot or very cold baths should be avoided. Four illustrative cases are described, and in conclusion the author says that angiosclerosis of the extremities in its gravest form, uncomplicated by a vasomotor neurosis, leads to spontaneous gangrene. If the angiosclerosis occurs in combination with a vasomotor instability and a tendency to vasomotor spasm, the syndrome of intermittent claudication results. This is characterized by the development of sensory (pains and paresthesia) and motor (weakness and rigidity) manifestations during functional activity with a rapid and permanent restoration to the normal during rest. The syndrome, however, has a wider and more general application to the whole circulatory mechanism and has been observed in relation to various organs of the body—heart, intestines, brain, kidney and eyes.

The Action of Formic Acid in Diseases Accompanied by Tremor.—One of the most troublesome symptoms that resist treatment in nervous diseases is tremor. Experiments performed by E. Clement (*Comptes rendus*, May 1, 1905), show that formic acid has a remarkable action on muscular tone, causing a sensation of increased muscular firmness. The author investigated the effect of formic acid in certain forms of tremor, in which the muscular weakness is marked. He used this substance with success in two cases of tremor, one a woman sixty-five years of age, and the other a man of seventy-two years. The first case had lasted ten years, and the second eighteen years. They were not examples of senile tremor, for the chin, lips and head were not affected. The tremor disappeared in rest, which excluded Parkinson's disease. On voluntary motion the tremor was quite exaggerated, it was not rhythmical, nor did it have the oscillations of muscular sclerosis. Both cases showed a loss of the patellar reflexes. In doses of four grains of the normal solution of formic acid, this substance produced results at once rapid and surprising. In two days the improvement was so marked that the patients could raise a glass to the lips without discomfort, and without spilling half of the contents. Improvement continued, although the tremor did not entirely disappear, owing probably to the long duration of the motor troubles. No other drug can compare with formic acid in its efficacy in this direction, not even hyoscyamine, which has hitherto been the drug by choice. It would be interesting to investigate the efficacy of this new agent in Parkinson's disease and in certain forms of chorea.

PRESCRIPTION HINTS.

Treatment of Cerebrospinal Fever.—The chief indications are to feed the patient on milk, adding brandy, if necessary; the bowels should be kept free. The spasms are best treated by hypodermic injections of morphine in three-minim doses, but they may also be controlled by a combination of bromides and chloral hydrate as follows:

R Potassii bromidi .....gr.xx
Chloral hydratis .....gr.xii
Syrupi aurantii .....m.xxx
Aq. chloroformi .....ad. ℥i

Misce. Ft. Mist. Sig. Two tablespoonfuls to be taken three times daily.

The following medicine may also be found of use in persistent cases of cerebrospinal meningitis:

R Potassii bromidi .....gr.xii
Potassii iodidi .....gr.x
Syrupi aurantii .....℥ss
Aq. dist.....ad. ℥i

Misce. Ft. Mist. Sig. Two tablespoonfuls to be taken three times daily after food.

Some physicians recommend the administration of potassium iodide in small or moderate doses as soon as the diagnosis of cerebrospinal meningitis is made. This should be continued three times a day.—*Practitioner*, June 15, 1905.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 5, 1905.

THE SIGNIFICANCE OF THE DIMINUTION OF FREE HYDROCHLORIC ACID IN THE STOMACH IN MALIGNANT DISEASE.

As a diagnostic sign, the absence or marked diminution of the free gastric hydrochloric acid has been accorded considerable weight in determining the presence of malignant disease of the stomach. The cause of this diminished secretion has been unknown, or has at least been attributed to an atrophy of the acid cells of the gastric mucosa, or an inhibition of their function by the ulcerative process in the wall of the stomach. That this absent, or retarded, secretion is not due to purely local causes, but is an expression of the constitutional disturbances underlying the malignant process, is the latest conclusion based upon experimental investigation.

This research was conducted by Prof. B. Moore (Proc. Royal Society, May 24, 1905), who studied the chemical composition of the gastric juice in cases of malignant growths, not only of the stomach, but also of other organs. He discovered that in malignant disease of any organ there is a marked diminution of free hydrochloric acid in the stomach in all cases below one per cent., or else an entire absence of this substance. The interpretation of this finding has suggested to the author certain interesting and, at the same time, important speculations on the subject of the etiology of cancer.

The chemical processes underlying the formation of hydrochloric acid in the stomach reside in the specific activity of the oxyntic (acid) cells of the gastric glands. These cells bring about the reaction between sodium chloride and disodium orthophosphate brought to them by the blood, with the formation of hydrochloric acid. Whatever the true explanation of this formation may be, there can be no uncertainty as to the fact that the precursors of hydrochloric acid exist in the blood, and that they consist of hydrogen and chlorine ions, in whatever combinations these may be. Now, it is known that hydroxyl ions also exist in the blood, which, accordingly, has both acid and alkaline reactions. Whatever causes tend to diminish the hydrogen ions in the blood cause a corresponding increase in the hydroxyl ions, and vice versa.

A number of explanations may be advanced to explain the inability on the part of the acid cells to bring about the chemical elaboration of hydrochloric acid. One of these is that the acid cells are atrophic; yet, while this may be true in cases of malignant disease of the stomach, there is no reasonable connection between such atrophy and malignant disease of other organs, in which deficient acid secretion also occurs. Such atrophy, moreover, has not yet been demonstrated. A second possibility has suggested itself, namely, that the malignant process inhibits in some way the function of the oxyntic cells. This explanation is shattered by the following observation made by Moore: "The radical operation was performed on a case of carcinoma of the breast, and many weeks later, after the patient had been discharged cured, the deficient secretion of hydrochloric acid still continued." The third explanation, which is the one advanced by the author, holds that the deficiency of acid secretion is the result of a diminution of the hydrogen ions in the blood. To quote this investigator, "the persistence of absence of acid secretion after the growth has been removed points to the view that the condition of the blood and most probably the absence or marked diminution of acid ions in it is to be regarded as a cause predisposing to growth formation, and not as an effect of the growth."

This view, which, if correct, will clear up the misty subject of cancer etiology, has a strong basis in experimental investigation. The researches of Jacques Loeb have clearly demon-

strated that each tissue depends for its health upon the chemical equilibrium of its immediate environment—the blood. This equilibrium consists in a delicate balance of the various inorganic salts. If one or more of these be increased, diminished or removed, there results a disturbance or an arrest of function. With respect to the effect of a diminution of the hydrogen ions and an increase of the hydroxyl ions, the following experiment, performed by Loeb, has an important bearing: He found that 1 c.c. of decinormal caustic soda (representing the hydroxyl ions), when added to 100 c.c. of sea-water, causes a remarkable increase in the development and growth of the eggs of the sea-urchin. A greater amount of alkali stops the growth entirely. It is thus seen that a slight increase in the hydroxyl ions acts as a powerful stimulus for cellular proliferation.

Inasmuch as an increase in the hydroxyl ions either absolutely or relatively is a necessary concomitant of diminution in the amount of hydrogen ions contained in the blood, which diminution has been found to occur in malignant disease, there are strong grounds for believing that this increase of hydroxyl ions plays an important rôle in the genesis of new growths. The tendency of recent research has been to attribute these abnormal cellular proliferations to a reversion of the cells to their habits in early embryonic life. There is, in fact, a latent tendency on the part of the living units to return, on the slightest provocation, to their primitive state of unchecked, riotous multiplication. It needs but a slight disturbance of the chemical equilibrium of the blood and other tissues to set in motion these inherited capacities of the cells for extravagant reproduction. Whether or not this stimulation is afforded by the reduction in the hydrogen ions and the increase of the hydroxyl ions of the blood, remains for future investigation to decide, yet the researches of Loeb and Moore are very suggestive in showing the chemical origin of new-growths.

The tendency to a recurrence of malignant disease, even after all traces of new-growths have been radically extirpated, strongly supports the hypothesis of the dependence of this condition on the chemical nature of the blood, which is not influenced by surgical procedure.

Apart from these speculative considerations, the discovery that there is a diminution or an absence of free hydrochloric acid in the stomach in malignant disease of any organ, has an important practical application. When this disease is latent, an examination of the gastric contents may give an important clue to the diagnosis. From the viewpoint of treatment, moreover, it would be interesting to note the effect of drugs that increase the number of hydrogen ions in the blood.

RADIATION THERAPY AND COMMERCIALISM.

A simple rehearsal of a recent set of incidents apparently not closely related to each other, and yet that on consideration will prove to have much more intimate associations than might be suspected, seems worth while giving for the sake of the lesson in certain modern medical advertising methods which it contains.

Some months ago there came the announcement widely heralded in all the daily papers of this country, that a very prominent educator, known to be suffering from a severe form of internal malignant disease, had been treated by various forms of radiation therapy and the result, it was said, had been eminently successful. Immediately there were editorials and special articles of many kinds hailing this new remedy for cancer and great hopes were raised in the breasts of all those who are suffering from malignant disease.

The medical press of the country paid very little attention to the sensational news, and mentioned it only to deprecate the raising of hope that would probably not be fulfilled. The announcement of cures for cancer is frequent enough, but cancer still continues to count its victims with even greater frequency than ever, and at the present time at least one in thirty of all who die, die from malignant disease. At the important meeting of the Association of American Physicians, at Washington, the only reference made to the recent sensational reports was the very conservative statement that cancers of the cecum usually run a rather slow and uncertain course and that though the opposite might be expected from the constant irritation, malignant disease of the large intestine in general, seldom developed to a rapidly fatal termination. Several of those who took part in the discussion on abdominal tumors, agreed with this statement but no reference was made directly to the case that has attracted so much attention.

Much as we might like it to be otherwise, the hopes that have thus been raised seem destined to be dashed to the ground quite as effectually as have similar expectations on previous occasions. This was, of course, what conservative physicians

and surgeons who knew the conditions and who realized the possibilities had expected, though they would only too gladly have been disappointed in this particular case. In the meantime, the sensational announcement of the cure supposed, has gone forth to work harm and to raise false anticipations surely doomed to disappointment.

There is also another feature of the case that is interesting. Not long after this cure was announced, there came news from Europe that the price of radium had advanced. Only a very minute amount of the metal in its pure state, somewhat less than one-half ounce, it is said, is available for any purpose whatever. It was declared that so many demands were made on this small amount for the various purposes of experimental research that the supply did not equal the demand, and a rise in price was the consequence. There are good grounds, however, for saying the stock of radium now on the market is in the hands mainly of a few persons, and that to use the familiar phrase, there is a corner in it. Not only this, but it is said that the sources of radium consisting mainly of various forms of pitchblende found in Central Europe, are all now practically controlled by a few individuals who have a commercial understanding in the matter.

It has been extremely interesting to note how much of free advertising has been given this commercial combination, because of the sensational character of the recent news item. That the whole thing has been worked up very well there is no longer any possible doubt. Whether the effort to create a new market for radium will be successful or not must depend upon further experiences. It is well, however, for physicians to realize just how this set of incidents hangs together and just what the significance of much of the newspaper comment really is.

Unfortunately the failures of the new method of treatment will never attain as wide publicity as the original announcements and so medical quacks will have the opportunity to play upon the feelings of sufferers and pretend to use radium as a curative agent, when some other quite harmless material is being employed. One conviction for the use of a simple solution of cinchona, instead of radium, has been obtained in New York. As it is extremely difficult to obtain radium now, it would seem as if to secure further convictions along this line, in cases where false pretenses of its use are attempted would be easy.

ECHOES AND NEWS.

NEW YORK.

Filtering the City Water.—Dr. Darlington advocates the filtering of city water, and has recommended to the Mayor that the city install a plant for that purpose.

Death-Rate Down Again.—The deaths in this city last week numbered 455, as against 639 the week before, and the death-rate was 20.68 against 28. For the corresponding week last year the rate was 20.66. Deaths from heart disease were again normal. The number of deaths from sunstroke fell from 151 to 27, while cerebrospinal meningitis, with 10 deaths, was at its lowest ebb.

Mr. Straus Reads a Paper.—At the recent meeting of the British Medical Association, Mr. Nathan Straus, of this city, read a paper on the need of milk for infant feeding in large cities and told what had been accomplished by his milk depots in New York. The paper created considerable interest among those who heard it, and will be published in the *British Medical Journal*.

Yellow Fever Precautions.—Although repeatedly assuring the public that there is no chance of yellow fever getting a foothold in New York, Dr. Doty makes assurance doubly sure by rigid inspection of all ships from southern ports, and the detention of any persons found with high temperatures. Numbers of such persons have been found on several ships from Gulf ports and from Central America, but none have developed the fever.

Fresh Air Charities.—Health homes, seaside cottages, floating hospitals, and children's summer homes have been filled to overflowing during the hot weather with poor women and their sick infants. During the recent hot wave the Children's Aid Society sent above 3,000 women and children to the seaside or to the country. There will be six weeks more of summer heat and suffering. The Children's Aid Society relies on the dwellers of this city for continued contributions. Checks may be sent payable to A. B. Hepburn, Treasurer, or C. Loring Brace, Secretary, at 105 East Twenty-second Street.

The President Visits Sea Breeze.—On July 29, President and Mrs. Roosevelt visited the Sea Breeze Home for the fresh-air treatment of children suffering from surgical tuberculosis. They came from Oyster Bay in the Sylph, and went ashore without any salute or other demonstration, as they wished to pay a quiet visit to the children. All the little patients who were old enough to know what was happening were delighted with the honor paid them, and the President's party went away enthusiastic about the work being done there. Mr. Roosevelt said: "The hospital has room for only 45 children, and there are more than 4,000 cases of bone tuberculosis in the tenement house district of New York. The trustees are trying to raise a fund for a hospital which shall hold 400 patients. The Fresh Air Fund people are obliged to refuse admission to 2,000 or 3,000 applicants annually. I was immensely impressed by the work being done there. I feel that there can be few more beneficial works than that which is being accomplished both in connection with the Fresh Air Fund and this seaside hospital for tenement children suffering from bone tuberculosis."

A Novel Port Boat.—The port of New York will have as part of its public equipment, at an early date, a craft mainly for hospital purposes, the counterpart of which does not exist anywhere. The boat is mainly

designed for the work of transporting sufferers from contagious diseases to the hospitals at North Brother Island, and for this service the craft will have the most modern appliances that science can suggest, at the same time it will be fitted out with powerful pumps, and it is hoped that it will prove a great factor in the extinguishing of fires along the river fronts. It is also intended that the boat shall be used as a water-carrying craft, having a tank capacity sufficient to supply any of the public institutions located on the islands of the New York harbor in the event of an accident to the pipes affording the present source of supply. The new boat will be known as the Claudine, and will be 126 feet long and 30 feet beam. The hospital section will be on the main deck and will consist of eight rooms, each liberally endowed with windows. These rooms are laid out in such a manner that it will be possible to reach any one of them without passing through any of the others, thus preventing the spread of contagion as well as avoiding the disturbance of patients. On the upper deck will be quarters for convalescents and visitors, nurses and doctors attending patients on the boat, patients being returned to the city as cured, and an office for the physician in charge. A morgue will be located in the bow of the boat on the main deck. All of the rooms are of steel, and may be closed up as tightly as a steel box, to permit of being thoroughly disinfected when occasion requires. In the finishing of the interiors, all angles of shelves which might afford lodging places for dust and germs are eliminated. The pumping facilities of the craft in case of fire will be considerable, but in addition to this there has been left a clear space on the deck large enough to accommodate a city fire-engine, and in case of an emergency such an apparatus may be loaded on board and transported to any part of the harbor. The Claudine will be fitted with twin screws and will have a speed of fifteen knots an hour; the boat will be of light draught so that it will be possible to navigate in any part of the harbor. The new craft will represent an expenditure of $70,000. This boat is being built on Staten Island, and will be launched in a short time.

PHILADELPHIA.

Application for Hospital Charter.—Having conducted Roosevelt Hospital, 1815 Frankfort avenue, as a private enterprise for some time, Dr. Franklin Brady has now made application for a charter to make the institution a public hospital. Dr. Brady's associates are Charles Glanz, 1025 Market Street; Henry C. Kellner, 301 East Girard Avenue, and Amos Brady, 2009 North Thirteenth Street.

Fear of Outbreak of Typhoid Fever.—Since the change in the source of the water supply the residents of Holmesburg and the vicinity have taken extra precautions to avoid an epidemic of enteric fever. The water supply until recently was taken from Sandy Run, but since the Holmesburg Water Company merged with the Disston Water Company it is obtained from the Pennypacker Creek, which the residents say is polluted. Chief Medical Inspector A. A. Crains, without taking the change in the source of the water supply into consideration, tried to allay their fears by telling the residents that until the present time fewer cases of enteric fever have been reported from the section of the city in question than any other.

To Guard Philadelphia Against Yellow Fever.—Since the news of the outbreak of yellow fever in New Orleans has reached this port rigid quarantine has been established. Inspectors have received strict orders to examine every vessel regardless of the place from which it hails, but especial attention must be paid to those coming from Panama, Southern ports and India. Drs. Horning and McCool were instructed to hold vessels should any of the passengers or crew show the slightest symptoms of the disease. Dr. Henry D. Heller, State Quarantine Physician at Marcus Hook Station, feels confident that no cases will pass the scrutiny of his deputies. He believes the station of this State could scarcely be improved, and is prepared to combat the disease should any cases show themselves.

New Bids for the Municipal.—From his investigations Mayor Weaver has discovered that "graft" found its way into the letting of the bids for the new Municipal Hospital. Apparently there were two firms bidding, but in reality only one, because on one of the contracts the one firm bid low and the other high, while on the second contract the one bid high and the other low, so that each firm had its purpose pretty well "cornered." Then, too, each contract was so let that the work would not be completed because it was alleged that the city did not have enough money at the present time to complete the work. According to the plans arranged by the former Director Smyth, the Mayor said the new hospital would have cost $3,000,000. Everyone is at a loss to know why the Department of Public Safety let the bid for the construction of the hospital instead of the Department of Health. If Mayor Weaver finds, as announced, that the funds are insufficient nothing will be done until finances will permit; then new bids will be let to complete the hospital.

To Determine the Sources of Pollution in the Schuylkill River.—Working cooperatively, Health Commissioner Dixon and Director Martin have instituted searching parties on the Schuylkill River to determine if possible places which are sources of pollution. Dr. Dixon's party began at Reading and came down the river, while Director Martin's party began its search at Philadelphia and worked up the stream. The small tributaries of the river will be explored, notes taken and then a complete report will be sent to the Department of Health. From previous inspections, Phœnixville is regarded as an especially dangerous point, while Pottstown and Mill Creek are also thought to be menaces to the health of Philadelphia. Attention will also be paid to villages and to farm houses along the river; if refuse, now thrown in the stream, can be burned just as easily, those responsible for such acts will be asked to burn it. The State Department of Health will treat the Allegheny River in a similar manner, although this stream is in a better condition than the Schuylkill River.

War Upon Flies and Insects.—At the meeting of the Board of Health of Philadelphia the following resolutions were adopted: Resolved, That the chiefs of the divisions of nuisances, milk and meat and cattle inspection are hereby directed to visit all retail dealers exposing for sale in front of their properties meats, fish, vegetables, fruits, candies and cake, and to instruct the proprietors that covering of some suitable material must be provided to protect the goods so exposed from flies and insects generally. Resolved, That the chief medical inspector, nuisance, milk, and meat and cattle inspectors be and they are hereby directed to instruct the inspectors connected with their respective divisions to inspect regularly all manure pits of all stables, private or livery, that exist in their districts, and to give instructions to owners or keepers thereof that stables and pits must be kept in clean condition, and where the pit is on the exterior of the premises it must be kept tightly closed or screened with wire. If a stable is connected with the premises they

visit an inspection must be made and a report made to the chief of the division, who in turn will report to the chief of the Bureau. The assistant medical, nuisance, milk and meat inspectors will visit all places designated in the resolutions and will make a thorough inspection of the establishments referred to therein, as well as direct the owners or agents that they will have to comply with the new regulations.

CHICAGO.

Enlargement of Hospital at Fort Sheridan.—An addition to the Post Hospital at Fort Sheridan, which will cost approximately $19,000, and will contain two wards for contagious diseases, with a capacity of 36 beds, has been begun.

State of Chicago's Health.—According to the weekly bulletin of the Health Department for July 29, public-health conditions have again become normal. There were 109 fewer deaths reported during the week than during the previous week and the annual rate of 13.57 per thousand is 17.3 per cent. less for the week and 15.5 per cent. less than the average July rate of the previous twelve years. This average was 16.06 per thousand, the highest having been 26.94 in 1893 and the lowest 14.34 in 1900. The rate for the twenty-nine elapsed days is only 13.16 and the month promises the lowest July rate on record. A larger proportion than usual of samples of milk and cream were found below grade during the week. So far as the inspector's samples are concerned this was due to work in the Polish district. Six unvaccinated children, all under ten years of age, were removed to the Isolation Hospital. This is the lowest number of smallpox cases in any week since last fall. There are 47 cases remaining in the hospital; no death during the week and no case so serious as to make a fatal result probable.

Crime in Chicago.—City Statistician Hugo Grosser made public a day or two ago his figures for the first quarter of 1905, and Prof. John A. Fairlie, of the Department of Administrative Law in the University of Michigan, said that the report of the police department's activity, given in detail under a system devised by Mr. Grosser, was of great sociological value. The report shows that the greatest number of arrests of men and women were for larcenies, and that white Americans led the list, with colored Americans second. The total number of charges of larceny preferred were 1,310. Of violations of the city ordinances there were 8,892, of which white American men were credited with 4,733; white American women with 541; colored men, 505; colored women, 134; Germans, 531; women, 48; Polanders, 495; women, 52. Three American women and two of other nationalities essayed the confidence game and 10 women of all nationalities were accused of burglaries. Only one man was arrested during this period for selling liquor to minors or drunkards. Married men and women, according to the statistician, are more law-abiding than those unmarried, the score standing 8,359 single men, and 951 single women to 3,593 married men, and 536 married women. There was a decrease in the total number of arrests as against the same period last year, but an increase in the arrests for felonies.

GENERAL.

Panama in Tuberculosis Congress.—Dr. Ciro Urriola has been appointed to represent Panama in the international tuberculosis congress, which will meet in Paris next October.

Cholera Epidemic in India.—A serious epidemic of cholera prevails among the refugees from the famine-stricken districts of British India, who have been crowding into Madras for weeks past. Numbers of victims have been found dead or dying on the streets. The death-rate is 89.7 per 1,000.

Dr. Woods Hutchinson Removes.—During the past three years Dr. Woods Hutchinson has been a resident and practitioner in Portland, Oregon. Hereafter, however, he will be located at Redlands, Cal., as Consulting Physician to the Arrowhead Springs. Dr. Hutchinson will also lecture at the Medical Department of the University of Southern California, located at Los Angeles.

Cases of Yellow Fever Outside of New Orleans.—Cases of yellow fever have been reported in Louisiana at Bunkie, Bayou Goula, Shreveport, and Point Barrow. A single case occurred at Tampa, Fla., and one at Lumberton, Miss. All the patients were Italian refugees from New Orleans, and so far the disease has failed to get further foothold outside the infected city.

Typhoid Fever Spreads.—The epidemic of typhoid fever which is raging in the Bath Beach and Fort Hamilton sections of Brooklyn is said to be due to the improper sewerage and to bathing in the polluted waters of the lower bay. Physicians are greatly alarmed over the increased typhoid fever cases in that section. At Bay Ridge great concern is felt over a threatened epidemic, which the physicians have been fighting for several weeks. Polluted water is blamed for the conditions there.

Heavy Death-Rate.—Thus far the death-rate in New Orleans of the discovered cases and recorded deaths is almost 25 per cent. heavier than it was even in 1878 and approximating the percentage of 1854, the latter the worst yellow fever attack New Orleans has ever experienced. This is explained by the health authorities on the ground that the disease has existed almost entirely among Italians—and that among a class very ignorant, very suspicious, and very filthy. They have insisted, whenever not watched, in eating macaroni and bananas the minute the fever had passed, and have frequently dropped dead in consequence.

Menace to Oyster Industry in New Jersey.—Planters of the Shrewsbury oyster are aroused over an attack upon their industry. The State Board of Health has notified the Shrewsbury township health board of the danger arising from the practice of certain persons who empty their sewage into the north and south branches of the Shrewsbury River, particularly the South Shrewsbury. It is stated that the pollution of the water injuriously affects clams and oysters. Claim is made that an outbreak of typhoid at Oceanic was caused by the use of clams taken from the South Shrewsbury. The township board is advised to prohibit the sale of shellfish taken from that river.

Suffering from Quarantine.—New Orleans is said to be suffering more from the erratic quarantine arrangements of her neighbors than from the fever itself. These shift from day to day, and nearly every town has a different quarantine. Besides the local restrictions against the city, the fact that the fruit trade has been diverted to other ports by the detention ordinances issued by New Orleans has worked much hardship among the Italians, some 2,000 of whom were employed exclusively in handling such cargos. Considerable indignation is also manifest against Gov. Vardaman, of Mississippi, who insists on measures the most stringent between the two States.

Yellow Fever on the Isthmus.—Reports from the Isthmus continue to give additional cases of yellow

fever and occasional deaths, but the fact that no widespread epidemic occurs would indicate that the prophylactic measures taken there are successful in a degree at least. John Barrett, formerly Minister to Panama, and now Minister to Colombia, declared last night that the yellow fever would be driven out of the Isthmus. "The fight against yellow fever is like a great battle," he said. "Every effort is made to stamp out the disease. The people of the United States must not be impatient if the progress of the canal is slow. They must remember that the scene of operations is 2,000 miles away from the base of supplies."

Mosquito Pest Nearly Conquered.—Destruction of mosquito larvæ by petroleum and the weeding out of shrubbery in moist places where the insects breed at various summer resorts have made those places pleasant to live in where in former seasons patrons of hotels and residents of cottages were disturbed till they were made frantic by myriads of the pests. Reports from various points in New Jersey and Long Island prove that the mosquito is nearly conquered. Southampton and Babylon are freer than in twenty years past. All small streams and creeks about Lawrence and Cedarhurst, and those about the Rockaway Hunt Club, were thoroughly cleaned during the last spring, and the frequent use of oil, sprayed on mud flats at low water, has brought about the absence of the pests. At Spring Lake, N. J., notable work by the Board of Health and citizens shows that these efforts have been successful. The reclamation of low lands in the immediate vicinity of Atlantic City and the filling in of old cisterns and stagnant pools have practically stopped the mosquito from breeding there. The only invasions from which the resort suffers from these pests come when the land breeze blows them in from the country.

The Yellow Fever Situation in New Orleans.—The first days of the present month found New Orleans with a record of 79 deaths from yellow fever, and a total of 378 cases, all but twelve occurring among Italians, and all but one among the poorer class. All things considered, there is a disposition to take an optimistic view of the situation. The fever has not spread as rapidly as had been feared, in view of the quarter where it broke out and the length of time elapsing between its first appearance and its detection by the health authorities. It is believed now that all concealed cases have been discovered. Surgeon-General Walter Wyman, of the Public Health and Marine Hospital Service, returned to Washington at the first report of the fever to take charge of the situation, and the department has some of its best men in New Orleans. Surgeon White is in charge. The city as a whole responds enthusiastically to appeal for systematic prophylaxis, and the work of exterminating the *Stegomyia* and its breeding places is progressing rapidly. "We are fighting," said one of the business men, "to do more than simply save a few lives just now. We are fighting to kill the bugbear of quarantine that has checked every proposed development of the city's commerce. We are going to show that yellow fever can be stamped out."

American Association of Obstetricians and Gynecologists.—The American Association of Obstetricians and Gynecologists will hold its eighteenth annual meeting at the Hotel Astor, Longacre Square, New York, Tuesday, Wednesday and Thursday, Sept. 19, 20 and 21, 1905. Dr. Robert T. Morris, 616 Madison Avenue, Chairman, Dr. Samuel W. Bandler, 229 West Ninety-seventh Street, and Dr. James N. West, 71 West Forty-ninth Street, constitute the local committee of arrangements, one or all of whom will gladly furnish information to members and guests upon application. The following is a list of papers offered up to the present date: The President's address, by Howard Williams Longyear, of Detroit; title to be announced, J. H. Carstens, of Detroit; title to be announced, Magnus A. Tate, of Cincinnati; Personal Experience in Hysterectomy for Myofibroma of the Uterus, by Miles F. Porter, of Fort Wayne; title to be announced, J. W. Hyde, of Brooklyn; Diagnosis, by John B. Deaver, of Philadelphia; Treatment of Procidentia Uteri, by H. E. Hayd, of Buffalo; Perineal Injuries and Methods of Repair, by Joseph Price, of Philadelphia; title to be announced, H. C. Pantzer, of Indianapolis; Appendicitis as a Factor in the Diagnosis of Abdominal and Pelvic Diseases, by Rufus B. Hall, of Cincinnati; title to be announced, W. A. B. Sellman, of Baltimore; Indications for Hysterectomy in Puerperal Eclampsia, by Charles G. Cumston, of Boston; title to be announced, Edwin Walker, of Evansville; title to be announced, John Young Brown, of St. Louis; Papillary Cystadenoma of the Breast, by Edward J. Ill, of Newark; Normal Saline Solution and its Application to Conditions, by Walter B. Dorsett, of St. Louis; Colon Bacillus Leucorrhea, by Robert T. Morris, of New York; Gall-stones in the Cystic Duct, by L. H. Dunning, of Indianapolis; title to be announced, O. H. Elbrecht, St. Louis; Pelvic Infection —Etiology, Routes of Invasion, Pathologic Changes and Clinical Courses, by John B. Murphy, of Chicago; Surgery of the Liver, by William J. Gillette, of Toledo; The Treatment of Puerperal Eclampsia, by E. Gustav Zinke, of Cincinnati; The Evolution of the Anterior Transplantation of the Round Ligaments for Uterine Displacements, by A. H. Ferguson, of Chicago; title to be announced, H. Howitt, Guelph; Myomectomy, by W. P. Manton, of Detroit; title to be announced, Thomas B. Eastman, Indianapolis; Extraperitoneal Pregnancy; Three Cases of Prolonged Gestation; Operation by Marsupialization; Recovery, by Charles A. L. Reed, of Cincinnati; title to be announced, F. F. Simpson, Pittsburg; title to be announced, L. S. McMurtry, Louisville; Some General Principles in Conservative Pelvic Surgery, by J. F. W. Whitbeck, of Rochester; title to be announced, Charles L. Bonifield, Cincinnati; title to be announced, John D. S. Davis, Birmingham; title to be announced, X. O. Werder, Pittsburg; title to be announced, B. Sherwood Dunn, Easton; Observations Respecting Treatment of Face Presentations, by A. P. Clarke, of Cambridge; title to be announced, C. C. Frederick, Buffalo. All members of the medical profession are cordially invited to attend the scientific sessions. Howard Williams Longyear, President; William Warren Potter, Secretary.

OBITUARY.

Dr. WALTER I. BRADBURY, of Boston, the physician in charge of the State bath house, Nantasket Reservation, Nantasket Beach, Mass., was drowned while bathing in the surf on July 31.

Dr. GEORGE B. WOODSIDE died at New Harbor, Maine, July 28, where he was shot on Tuesday by Arthur, the fifteen-year-old son of Joseph McFarland, of Charlestown, Mass. Young McFarland, who was passing a vacation at New Harbor, was discharging a revolver, when the physician, driving by, received a bullet in the right temple.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-sixth Annual Meeting, held at Portland, Oregon, July 11, 12, 13 and 14, 1905.

SECTION ON PRACTICE OF MEDICINE.

SECOND DAY—JULY 12TH—*Continued.*

(Continued from Page 233.)

SYMPOSIUM ON ANIMAL PARASITES AND TROPICAL DISEASES.

Amebic Dysentery in the Philippine Islands.—Dr. W. E. Musgrave of Manila, P.I., discussed the symptoms, diagnosis and prognosis of dysentery of tropical character due to the ameba. Dr. Musgrave said that the most important period of the disease is that in which it is latent. In a number of cases the ameba is present in the intestines for a long period, causing only vague intestinal symptoms, and then, under favorable conditions, lighting up severe and sometimes even fatal dysentery. The absence of diarrhea is one of these features of these cases. This latency may represent an incubation period, but it seems much more likely that it should be considered the first stage of the disease in which the lesions are high up in the colon and give no dysenteric symptoms. Such affections may be dangerous and death has occurred after only a few days of acute symptoms, apparently a fulminant case of the disease.

High Localization.—The most prominent feature of these latent cases is the fact that the ameba causes its lesions only in the ascending and transverse colon and in the cecum. The symptoms then are pain and tenderness, referred to the course of the colon. No ameba is found in the stools unless a hydragogue cathartic is given. The absence of the ameba does not make a negative diagnosis of amebic dysentery. In the case of a young married woman seen recently the only symptoms were those of general lassitude, and there was absolutely no diarrhea. After a cathartic was given amebæ were found abundantly. Two months later some discolored blood occurred, and it was evident that ulcerative stage of the disease had been reached. Under injections there was improvement, and then there was diarrhea after an interval during which she was not treated owing to absence in Japan. Ten months after the amebæ were first seen sudden dysenteric symptoms developed, and the patient died in three days. At the autopsy old ulcers were found in the upper colon from which there had been a sudden general infection of the intestines.

Cure Without Treatment.—The Philippinos themselves evidently have amebæ in their intestines for many years without serious symptoms. Not infrequently healed ulcers are found at autopsies late in life, showing that the disease can be spontaneously cured without active treatment. Frequently death takes place from inter-current disease, and then the ulcers are found present in the cecum and transverse colon. When treatment is instituted early liver abscess occurs very rarely. In fact, American physicians have been surprised at the few liver abscesses that have occurred in cases under their care. Dr. Musgrave himself has not seen a single case of liver abscess in a thousand patients treated by him.

Diagnosis.—The diagnosis of the disease must be made, if possible, with the microscope. The clinical picture is helpful, but may deceive. Abdominal soreness along the course of the colon is singularly the most valuable symptom. In early stages of the disease this soreness is likely to be localized over the cecum and the lower part of the ascending colon. Nausea and indigestion are dubious symptoms, though loss of weight while patient maintains a good appetite must always excite suspicion, especially when the patient has recently come to the tropics. Early treatment is the most important thing for the disease; for in cases treated early no infection of the liver takes place. According to statistics, 20 per cent. of untreated cases develop liver abscess. When there is any doubt salts should be given freely and the stools carefully examined. Castor oil and the use of enemata for diagnostic purposes are not likely to be of much service. The speculum is helpful only when the lesions are in the rectum and lower bowel.

Prognosis.—The prognosis cannot be lightly made. There must be careful weighing of all the conditions. If the latent period of the disease has existed for a long time, then the prognosis is bad. In young adults recently affected the prognosis is always good. The children of the natives recover without treatment. To wait until blood and mucus occur in the stools always adds to the seriousness of the prognosis. Prompt treatment by injections is not only effective for symptoms, but prevents complications.

Pathology and Etiology.—There is no doubt now that this form of tropical dysentery is due to the presence and the pathological activity of the ameba. There used to be some doubt about this, but it has disappeared under the continued investigations. The ameba as a normal inhabitant of the intestine does not occur under ordinary circumstances. The walls of the gut under the influence of ameba become thickened and edematous. The first lesions seen are punctate in form, and capillary hemorrhages may be present. After this comes an erosion of the superficial layers of the mucous membrane. Sometimes the organism penetrates through the epithelial layer without producing any lesion and is found lying on the basement membrane. The distribution of the ulcers is rather characteristic, and is not entirely limited to the colon. Ulcers have been found in the ileum as much as 40 cm. above the valve. Not infrequently the cecum is found nearly covered with ulcers, and then the appendix is also sure to be affected.

Importance of Latent and Early Mild Cases.—Dr. George Dock, of Ann Arbor, Mich., said that Dr. Musgrave has thrown more light on the diagnosis and pathology of amebic dysentery than any other investigator. The importance of calling attention to the latent and early mild cases cannot be overestimated. These cases are entirely free from dysenteric symptoms, no amebæ are to be found in the stools, no blood even altered in character is passed, and yet amebic dysentery exists. If an ounce of Carlsbad salts be given the amebæ may be found in the stools. It is sometimes thought to be difficult to find the ameba, but salts will always bring it if it is present and no warm stage is needed on the microscope for its recognition. The stools should be received in a flat porcelain vessel, and then suspicious portions may be picked out.

Vigorous Treatment.—Dr. Dock has seen a number of cases of returned soldiers who had served in the Philippines. The affection is easy to stop after beginning, but difficult of treatment later on. Vigorous catharties form an important part of the treatment. Large injections should be given, and Dr.

Dock has found strong salt solution almost as good for this purpose as the silver enema, which is so often recommended. It is important that patients should not be allowed to become constipated. Ipecac is useful in many cases, and may be given with salol with excellent effect. In one case Dr. Dock gave thymol for uncinaria. Amebæ were also present, and disappeared at the same time. It must not be forgotten amebic dysentery may occur in cold climates, and is by no means limited to the tropics, and that a number have now been reported in many parts of the country in patients who have never lived outside of the United States.

Dr. Williams, of San Francisco, said that in a number of cases that he had seen during a residence in the Philippines, one striking feature seemed to be that liver abscess did not occur so frequently in women as in men.

Dr. Shattuck, of Boston, said that he had one patient under observation, suffering from true amebic dysentery, with many amebæ in the stools, who had never lived out of New England. The disease, then, is not essentially of the tropics, and it is probable that many cases are being missed in various parts of the country, and that the dysentery is considered to be due to other causes.

Sudden Death in Amebic Dysentery.—Dr. Claude A. Smith, of Atlanta, Georgia, related the case of a patient admitted to the hospital suffering from severe dysentery, in which death took place on the day after admission, and before any definite study of the condition could be made. At the autopsy a large number of old amebic ulcers were found, besides a fresh infection extending along most of the colon. It seems not unlikely that some of the sudden deaths that occur in hospitals elsewhere may be due to this affection. It emphasizes the necessity for careful study of the intestines of all cases of sudden death.

The Ameba in Manila.—Dr. Musgrave said that the ameba occurs in the water of Manila. Occasionally these amebæ in water are supposed not to be pathogenic. Whenever amebæ found in the stools contain red blood cells it seems not unlikely that they are pathogenic, though this has not been definitely settled as yet. An ameba that seemed to be non-pathogenic after passage through the monkey was found to contain red blood cells. Later, however, this ameba seemed to revert to its orinigal less harmful condition. The most important thing about amebic dysentery is that it may be cured completely if well and early treated. So far Dr. Musgrave has had no recurrences in his cases. The large number of Philippinos that come to autopsies with scarred bowels indicate that there may be recovery from the disease even without treatment, and that, therefore, the outlook is hopeful. Dr. Musgrave has seen ameba occurring in the stools of what was considered to be a normal bowel, but always later the development of the case showed that lesions were present.

Infection in Uncinariasis.—Dr. Claude A. Smith, of Atlanta, Ga., discussed the mode of infection in this disease, and exhibited lantern slides of certain experimental demonstrations of the infection through the skin by means of this parasite. Dr. Smith said that the uncinariasis is one of the most common diseases in the South, though its presence has not been suspected until recent years. In country districts particularly the parasites occur very frequently in the stools, and as there is no proper disposal of sewage, opportunites for infections are frequent. The larvæ of flies burrow in the stools, and so produce avenues of entrance for oxygen, in the presence of which the eggs of the parasite develop very rapidly. This combination of two insect pests is not uncommon in nature, and the mode of life of one seems to be calculated to help the other.

Investigation of Stools.—If enough soil be added to the stool to destroy the odor, this supplies enough oxygen to enable the eggs to develop well. Under these circumstances the larvæ of this parasite develop very rapidly and in large numbers. If kept in a deep jar they climb up the side and evidently develop a considerable range of movement. This shows that the larvæ might also climb up on grasses and vegetables and perhaps produce infection in the intestinal tract of persons consuming these substances. As none of the animals are liable to this disease, however, so far as investigation has gone, cannot be considered to be important.

Experimental Demonstration of Infection.—Dr. Smith found that a large proportion of moisture is necessary to have the larvæ develop well and actively. At certain seasons there is not enough moisture, and consequently infection is rare. When a certain amount of fecal matter containing enough soil to make it inodorous, but containing a large number of uncinaria larvæ, was applied to the back of the wrist of an individual who offered to undergo the experiment, infection occurred. For six days the material containing the larvæ were placed on the patient without any effect. On the seventh day, however, he complained of itchiness and irritation. This developed into a stinging sensation. The material was allowed to remain for an hour, and then the spot beneath it became red and hyperemic. After twenty-four hours some swelling was noticed and this swelling extended also to the back of the hand. After the hyperemic stage vesicles formed and the edema became marked.

Infection of the Intestines.—For several days the area of irritation on the back of the wrist was allowed to remain untreated, and then was treated just sufficiently to prevent itchiness. Six weeks after the placing of the infected material on the back of the wrist the eggs of the parasites were found in the stools. After a time the patient demanded treatment, as he was losing weight, and then some 1,300 larvæ were found in his stools. It is evident that this very extensive infection occurred entirely from the irritated patch on the back of his wrist.

Ground Itch and Infection.—It is evident that uncinariasis occurs as the result of infection through the skin, and it seems not unlikely that this is the only method of infection. Children in country districts who go barefoot become infected, and then by scratching spread the infection. Secondary infection with bacteria occurs, and this seems to favor the progress of the previous parasite. After some weeks there is disturbance of digestion, and the whole clinical picture, due to the presence of the parasite, develops. Fortunately the weather in north Georgia favors infection only at two periods of the year—in the late spring and early fall, when there is a moisture with sufficient warmth. In south Georgia the opportunities for infection are more frequent, and the disease is consequently commoner.

American Achievement in Disease Eradication.—Dr. Richard Cabot, of Boston, the Chairman of the Medical Section, then said that there were two great achievements in medicine effected since the Spanish-American war, of which Americans may well be

proud. Cuba has been freed from yellow fever, from which the island had been a sufferer for four centuries. American physicians are engaged in the work of freeing Porto Rico from the anemia due to uncinariasis, which has been a scourge of the island for as long almost as history runs. Two physicians particularly, Drs. Ashford and King, are engaged in an active campaign against this disease. They travel around with a hospital equipment of tents, camp outside of a town, and are practically treating a whole people. Those who suffer from the severer forms of the disease are taken directly into the hospital tents, while those with less severe symptoms are given the remedies for use at home. Their work illustrates what may be accomplished even when a disease is so endemic as this anemia of Porto Rico is, and shows that modern advance in medicine can accomplish wonders. Only the work of Reed and Carroll, in the investigation of yellow fever, seems to be of equal importance to this.

Uncinariasis in California.—Dr. Brown, of San Francisco, said that there are three classes of cases who suffer from this disease in San Francisco. The first class consists of Mexicans, some poor, but some of the better classes. The second class are soldiers who served in the tropics, were discharged without symptoms, and yet have later developed signs of the disease. The third class consists of Porto Ricans who were sent to Honolulu in order to replace Japanese laborers, but who did not succeed as was expected. In the cases seen in San Francisco one of the most significant features is the seriousness of the symptoms that may develop, yet with very few parasites present. In one case only seven parasites were found, and yet a nearly fatal anemia had occurred. Among the Porto Ricans in San Francisco it is noted that no infection occurs among the children, so that it seems probable that only a cutaneous mode of infection brings the disease into the system.

Modes of Infection.—Dr. Smith said that it is not as yet decided whether there is some other mode of infection besides that through the skin. In answer to a question he replied that the parasites seem to travel from the point of entrance into the system through the veins. In his experimental observations some of the veins for a distance around the area of inoculation became reddened so that red streaks were present. These resembled phlebitis, however, and there was no infection of the lymphatics. In the blood stream the parasites pass through the lungs and heart, and so find their way to the intestines. In the South, during the summer time, outside of the cities all of the children of both rich and poor go barefoot, hence the frequent possibility of infection. It is reinfection, however, oftener repeated, that leads to the severe symptoms of the disease. City children of vigorous constitution recover from a single infection. Country children are infected over and over again, until they develop anemia of a severer type.

Course of the Disease.—It is often said that as children grow older in the country they outgrow their tendency to this anemia. As a matter of fact, however, what happens really is that they begin to wear shoes, and then there are no further infections, and their resistive vitality overcomes the disease. It is a mistake to consider that children suffering from the disease are necessarily either lazy or stupid. They may indeed be very bright. They are not able to do severe manual labor because their anemia prevents them from carrying sufficient oxygen to enable them to take muscular exercise to any extent. One of the students of the Medical School, in Atlanta, though a sufferer from the disease in a severe form, led his class, and was one of the brightest students. Before studying medicine, he had taken all the prizes in the High School.

Third Day—July 13th.

Symposium of the Stomach.

Physiology of Nutrition.—Dr. Frank Billings, of Chicago, said that a recent investigation seems to make clear that there has been too high a standard of the amount needed for the balance of nutrition in human beings. This standard has been too high, especially with regard to the proteids. These are the materials that are obtained from meat, eggs, fish, peas, and beans, and the like. Proteid material is used for tissue building, while the carbohydrates and fats are consumed as the fuel of the body in order to supply the energy necessary for the work done. When too much proteids are consumed they are changed into crystalline substances in the circulation which have a somewhat toxic action and cause irritation when excreted. The fats and carbohydrates do not produce any such harmful results, and only lead to an undue accumulation of material, but without irritation.

Instinct and Appetite.—How far instinct can be left to guide us in the selection of food and the amount taken has always been a question. Tradition seems to indicate that instinct can be trusted. There has long been an impression, however, that mankind, where it can obtain it, eats too much, and especially too much meat and similar material. Dr. Chittenden, of Yale University, undertook an investigation of nutrition, with the idea of determining how much proteid material was necessary in order to maintain bodily equilibrium and full strength and not have any expensive waste. As the result of his investigations he found that much less proteid material was needed than has so far been considered necessary. His attention was attracted to this subject by the suggestions of Fletcher, who has shown that if mastication were more complete, and the food was brought more intimately in contact with the palate, then there was less appetite for and less consumption of proteid foods.

Conditions of the Experiment.—Dr. Chittenden took three classes of persons for his experimental observations. The first were five members of the faculty of Yale University—men of sedentary habits and mental occupations. The second group consisted of athletes, many of them the best athletes in Yale University, whose diet could be regulated for the purpose. These represented a group doing intense labor and using up muscular substance. The third group consisted of United Stated soldiers detailed for the purpose, who were also given regular exercise in the gymnasium, and represented people who take an ordinary amount of exercise. Careful observation of these three groups under the ordinary diet for three months, and then on a diet in which there was considerably less proteid material than before. It was found that the balance of healthy nutrition could be maintained with scarcely more than one-half the proteids originally consumed.

Creatinin as the Criterion of Nutritional Equilibrium.—In these experiments it was found that while there was a reduction in the amount of nitrogen

excreted this did not affect all the elements of excretion to the same degree. The amount of urea in the urine was markedly decreased. The amount of ammonia nitrogen was relatively increased. The amount of creatinin nitrogen was relatively increased, but remained essentially the same during the changes of diets. The uric acid nitrogen was diminished, though relatively increased, and evidently corresponded with the excretion of urea. It would seem then that the creatinin represents the criterion of metabolic equilibrium. Folin has found that the extra material of proteid character that is absorbed from the stomach is not oxydized, as was once thought, but is hydrolized, and then passes out through the kidneys. It thus serves only as an irritant, and does no good at all in the system.

The Overeating Habit.—There seems to be no doubt that practically every one eats more proteid material, that is, more meat and similar solid substances, than is necessary. The irritation produced by this useless material can be noted in various painful conditions of joints and muscles, usually spoken of as gouty or rheumatic. In Professor Chittenden's experiments it was noted that when less proteid material was consumed there was much less complaint of these pains, and, indeed, the subjects of the experiments had a sense of well-being not previously possessed. The limitation of diet leaves an absolutely free choice, especially as regards the fats and carbohydrates, and only affects the amount of proteids, reducing it by one-third.

Study of the Gastric Contents.—Dr. George Dock, of Ann Arbor, Mich., said that the study of the chemistry of the gastric contents has unfortunately been neglected. It is sometimes thought to take too much time and require much apparatus. This is not true, however, and the chemistry of the stomach may be studied with very simple means at hand. Some physicians fear that they will not be able to pass the stomach tube properly and with ease. In many thousand cases, however, Dr. Dock has only failed twice, and in both of these he did not have a proper oportunity to use his persuasive powers on the patient. The usual trouble is that there is a lack of training with regard to this investigation of the stomach, and physicians hesitate to take it up for themselves later. There has been much disappointment because the study of gastric chemistry does not give any pathognomonic signs, but this is only what may be expected, since it is becoming more and more realized that it is careful study of all patient's symptoms, and not any one, that enables the physician to make the diagnosis.

Ordinary Reactions.—It was unfortunate that in the early days of the study of the chemistry of the stomach that the announcement was made that hydrochloric acid was absent in cancer. In a large proportion of cases this remain true, but in many cases hydrochloric acid may be found all during the course of gastric cancer. It may even be present in excessive amounts of gastric cancer. An excess of hydrochloric acid is not necessarily present in ulcer of the stomach, though commonly there is an increase in this secretion. Great variations occur in individual cases, and even from time to time a distinct difference in the amount of acid may be found. The investigation of the stomach contents in functional diseases of the stomach.

Lactic Acid and Organic Acids.—On examination with regard to the presence of lactic acid a test meal free from lactic acid should be given. Dr. Dock has found shredded wheat biscuit excellent for this purpose, and it is withdrawn forty-five minutes after its ingestion. In this, however, as in other features of the chemical investigation of the stomach, too much significance must not be given to either negative or positive results and several trials may be necessary to determine any one point.

Limited Value of Chemical Investigation.—Without other investigations of the stomach contents, the chemical reaction would give very little positive information. If Dr. Dock had to give up the other means of investigation he would consider the chemical as of little service, and would prefer to do away with it. Investigation of the stomach contents, even microscopically, will readily show the presence of excessive mucus, and it should carefully be determined whether this mucus comes from the gastric or the respiratory tract. The presence of pus in the gastric contents can also be readily recognized. But careful investigation must be made to determine that it does not come from the mouth or from the throat. The presence of altered blood in the gastric contents is extremely important. Occult blood can be found better by investigation of the stools.

Microscopical Examinations.—Bits of mucous membrane are frequently contained in the stomach contents, and may give valuable information. It takes some time, however, to harden and examine them properly, but in doubtful cases this should be done. The bacteria present in the gastric contents are of the greatest importance, and must be carefully investigated. Yeasts and sarcinæ are commonly found, and are significant, especially in stagnant conditions. Occasionally protozoa may be found in the stomach contents of sufferers from stagnation of the gastric contents, from whom material is removed before the giving of a test meal. The freezing point of the gastric contents is not of importance though it has been carefully investigated. With regard to other body liquids, the freezing point has not proved of as much importance as was thought.

Conclusion and Demonstration of Mastication.—Dr. Dock said that a single examination of the gastric contents is of little or no importance. Very often no information at all is obtained, yet a negative result enables the examiner to collate this with other information. A very important feature of the investigation of the stomach contents is the demonstration to patients of how insufficiently they masticate their food. If an ordinary meal be removed several hours after it has been eaten, the patient will often be surprised to find what large pieces of meat and potato he has swallowed without realizing that they were going down unchewed. After this it is usually much easier to persuade them that they need to masticate their food more thoroughly, and commonly an immediate improvement in the gastric symptoms occurs as a result. If for no other reason than this it would be advisable to pass the stomach tube in certain cases of bothersome indigestion.

Non-Gastric Diseases; Gastric Symptoms.—Dr. J. H. Musser, of Philadelphia, said that the number of cases that come complaining of gastric symptoms through suffering from affections of other organs is very large. It is extremely important to differentiate these two classes of affections. Practically every organ in the body may reflexly affect the stomach. The eye may cause stomach symptoms, as is well known, and fitting with glasses may relieve dyspeptic symptoms that may have existed obstinately, in spite of all treatment, for a long time. Affections of the

nose and throat may in like manner cause stomach symptoms, and this is illustrated by the frequency among users of tobacco susceptible to its influence. Children suffering from adenoids are especially likely to have gastric symptoms. The ear is a special source of stomach reflexes, and even this short review shows that it may be necessary to call in the aid of many specialists to help in the diagnosis of the cause of supposed dyspepsia.

Nervous Diseases and Gastric Symptoms.—The most fruitful source of gastric symptoms, where the primary affection exists in another organ, are those traceable to the nervous system. Sometimes the first symptom of locomotor ataxia is a gastric crisis which seems to be an acute attack of indigestion. The cause may be readily overlooked, and even surgical operations have been done in these cases without recognizing, until afterward, the real cause at work. Brain tumor may produce nausea and vomiting and other acute symptoms. And epilepsy may be responsible for explosive gastric symptoms of the most elusive character. Rumination is not uncommon in milder cases of epilepsy, and undue chewing is another symptom that has been traced without cause to the stomach. In fact, there are no reflex gastric symptoms that deserve more attention than those which come from epilepsy. Dr. Spiller has shown how frequently and how insidiously these symptoms may develop and the additional fact that up to the present time they have not infrequently been missed.

Gastric Symptoms in the Heart.—Whenever there are obscure gastric symptoms it is especially important to examine the heart. Not a few of the cases of acute indigestion, or so-called acute gastritis with pain, and prostration, especially in the old, are due to cardiac lesions of various kinds. Sometimes these cases end fatally yet unexpectedly, and without a post mortem it is difficult to understand just why the sudden fatal termination has occurred. Careful auscultation of the heart should always be part of an examination of a stomach case presenting obscure symptoms, especially with severe exacerbations.

Gall-Stones; Gastric Symptoms.—Of recent years it has been found that gall-stones are much more frequently the cause of what have been called stomach symptoms than what was formerly thought. Sometimes the symptoms point entirely to the epigastrium, and not to the region of the gall-bladder. Gall-stones may be especially obscure in their symptoms, and this fact must always be borne in mind, especially in cases where, according to the history, there has been the opportunity for the development of gall-stones, as after typhoid fever. Affections of any portion of the intestinal tract may curiously enough give rise to symptoms that may seem to be attributable to the stomach alone, though the stomach itself may be comparatively unaffected. Constipation is especially likely to be reflected in indigestion of one kind or another, and not infrequently directed to this fails until there has been proper regulation of intestinal evacuation. The portions of the intestinal tract farthest away from the stomach seem to be most likely to produce gastric symptoms. This is especially true of cecum and colon, and in recent years attention has frequently been called to the fact that affections of the appendix, when long continued, are especially prone to give obstinate symptoms.

The Genito-Urinary Tract.—Reflexes from this tract are of course the well recognized as producing stomach symptoms. The subject has been exploited in recent years, though, of course, the nervous condition produced by genito-urinary trouble may be the connecting link between the genital tract particularly and the stomach. Wherever anything serious exists in this tract especial attention must be directed to it. In recent years Dr. Musser has found that gonococcus infections of chronic character are especially likely to produce stomach symptoms of various kinds. A secondary toxemia often develops and proves various to treatment. When gastric symptoms, especially in young persons, fail to respond to treatment, careful investigation should be made as to the possibility of the existence of focus of gonococcus infection anywhere in the genito-urinary tract. The prostate should be examined and the urethra carefully investigated by the specialist, otherwise there will be no successful management of the gastric manifestations.

Systemic Conditions and Gastric Symptoms.—It must not be forgotten that anemia always produces gastric symptoms, and that the loss of appetite and perversions of appetite which occur in anemic conditions are directly dependent upon the blood, and cannot be treated by the ordinary remedies for the stomach. It will often be found in anemic conditions that the gastric symptoms will not yield to ordinary tonics, but will be relieved at once by the use of iron and of remedies directed to the correction of the blood condition. In recent years it has been pointed out that many of the cases of chlorosis are really the initial stage of tuberculosis. This calls attention to the fact that the preliminary symptoms of tuberculosis are often gastric. Only too frequently the disease begins insidiously in stomach symptoms, and its true character may be missed entirely unless the physician has his suspicions aroused and looks carefully for the earliest signs of pulmonary involvement. Practically all of the infectious diseases give rise to gastric symptoms. This is true of syphilis as well as of the other infectious diseases, and the stomach symptoms are as manifold as the other manifestations of this protean disease. Even the mild infections may be ushered in by sudden vomiting and by nausea. In children this sudden vomiting may be accompanied by convulsions and some serious stomachic conditions may be feared when it is only the beginning of one of the ordinary infectious diseases.

Intestinal Parasites and Gastric Symptoms.—Practically all of the intestional parasites may cause gastric symptoms with perversions or loss of appetite, or at times greatly increased appetite, yet without gaining weight. All of the various forms of tapeworm produce that symptom, though the clinical picture differs greatly in different individuals, and requires careful analysis. In recent years the frequent occurrence of uncinariasis in this country has come to be recognized, especially at the South, and gastric symptoms are one of the commonest manifestations of an early stage of the disease. Needless to say, in any of these cases the direction of treatment to the stomach entirely is sure to fail, and the patient's improvement depends on the recognition of real pathological condition at work.

Intoxication and Gastric Symptoms.—All of the intoxications produce gastric symptoms. This is especially true of lead, though, of course, mercury and the other metallic poisons produce symptoms. It is not uncommon to find that the serious foundation achylia gastrica is present without any other

cause than the presence of lead in the tissue. In milder cases of lead intoxication, however, the gastric symptoms may be marked, especially with susceptible individuals. Indeed, these may be the first and only symptoms manifest for some time, and require careful investigation in order to discover their cause.

Neuroses.—Practically all of the neuroses produce definite gastric symptoms, though the clinical picture may vary greatly from day to day. Exophthalmic goiter is practically always accompanied by gastric and gastro-intestinal symptoms and, indeed, these are sometimes in severe cases the cause of the later neurotic symptoms. At times the rapidity of heart present together with the gastro-intestinal symptoms are the only ones that herald the beginning of the more serious development of Graves' disease. Gastric neuroses may occur apparently without any cause outside of the stomach itself. Crises of pain and vomiting may occur that seem to indicate some serious involvement of the nervous symptom, and yet prove, after careful study, to be due only to hysteria or the advanced forms of neurasthenia or nervous exhaustion. In the midst of this discussion of neurotic gastric conditions it must be borne in mind, however, that occasionally definite local causes are found for symptoms that seem at first to be due only to the nervous system. There seems to be no doubt, however, that a local focus of suppuration sometimes produces a toxemia the symptoms of which are noticed more in the stomach than in any other organs. Nature seems to attempt to eliminate toxins in the circulation through the stomach wall and the presence of these poisonous materials in the stomach gives rise to symptoms. It must not be forgotten that the local focus of suppuration may be in the mouth due to the presence of carious teeth or some one of the many forms of peridental suppuration that have been investigated in recent years. Oral suppuration may indeed produce serious stomach symptoms, but even severe general conditions and in all cases of stomach disturbance the mouth must be carefully investigated.

Surgical Intervention in Acute Symptoms.—This constitutes one of the most serious problems that the physician has to deal with. The gastric symptoms may be so acute as to lead both surgeon and physician astray. Vomiting with blood in the vomit may occur to such an extent as apparently to make the diagnosis of gastric ulcer sure beyond all doubt, yet on exploratory incision condition present may prove to be nothing more than a severe congestion of the stomach consequent upon cirrhosis of the liver. In the same way uremia may produce gastric symptoms that simulate ulcer of the stomach or severe gastritis. In a recent case the epigastric pain was so typically localized, the vomiting with blood and the presence of collapse seemed surely to indicate the necessity for surgical intervention for perforating ulcer of the stomach, yet fortunately the remission in the symptoms stayed the surgeon's hand, and when death took place four days later from uremia, the autopsy showed that there was no organic disease of the stomach. In the same way cases of locomotor ataxia may produce the impression that surgical intervention is needed. Indeed, there are a good many cases now on record in which operations have been performed during the course of the gastric crisis of tubes, and a careful investigation of the nervous system with reference to this must be made in all cases where there is doubt. As a matter of fact, all the organs of the body may produce symptoms reflexly referred to the stomach. Probably a large proportion of the cases of supposed indigestion are really due to stomach conditions primarily, but to affections of other organs reacting directly or through the nervous system upon the stomach.

Stagnation of Stomach Contents.—Dr. Chas. G. Stockton, of Buffalo, N. Y., discussed the question of food stagnation from all causes. It may be considered to be present whenever the stomach fails to empty itself properly of its contents. The material of an ordinary meal should be disposed of by the stomach in four or five hours. If any of it stays after that time a mild amount of stagnation must be considered to be present. Riegel sets the limit at seven hours for the disposition of an ordinary meal. If patients complain then of eructations of food that has been eaten longer than this, then a certain amount of stagnation is present. Serious stagnation, however, causes retention of food for twelve to twenty-four hours, or even longer. The most important symptoms are a sense of distress, with considerable eructation of gas, and even of vomiting. The general symptoms are those of lassitude and feeling of depression consequent of lack of nutrition and the absorption of unsuitable material. The most important causes are obstruction of the stomach outflow with consequent dilatation. At times, however, there may be marked obstruction at the pyloric orifice, yet very little dilatation. It used to be considered that dilatation always occurred in cases of food stagnation, but this is now known not to be true. As a matter of fact, dilatation occurs only in persons who are predisposed to the development of this condition. The most important cause is a weakness of the muscular layer. The condition is prone to develop in members of the same family, so that there seems to be an hereditary weakness of the muscular wall of the stomach. It occurs particularly in those who overload their stomachs, who take large amount of fluid with their meals, who eat very hurriedly, masticating poorly, and, as a consequence, allowing large portions of food to reach the stomach which cannot be easily disposed of, and block the issue of food from the stomach. The eating of coarse food may produce a similar result.

Gastric Weakness in Convalescence.—During condition of convalescence the stomach seems to be predisposed to dilatation. In a recent case a typhoid fever patient ate heartily of a Christmas dinner, and as a consequence suffered from acute dilatation of the stomach. Persons in weakened conditions, after periods of starvation and after a severe illness, during which time much food has not been taken, must be warned of the possibility of this, or otherwise the foundation of a serious enduring gastric condition may be laid.

Stomach Obstruction.—The most important forms of stomach obstruction are due to tumors of the stomach, especially of the malignant variety, and to cicatricial contraction of the stomach walls usually consequent upon gastric ulcer. At times there is spasmodic contraction of the orifice of the stomach as a result of the presence of an active ulcer. The condition of spasmodic contraction of pylorus is not well understood. The presence of even a small ulcer may give rise to such severe contraction as to prevent the exit of food. On the other hand, the irritation of coarse or badly masticated food may in the course of time give rise to a hypertrophy of

the pylorus, which may make it extremely difficult for the stomach to pass on its contents. As a result, there may be at first some hypertrophy of the muscular wall of the stomach, after which dilatation may develop. More important even than the conditions within the stomach, in many cases, are conditions that cause obstruction from without.

Perigastritis.—Not infrequently inflammatory conditions of one kind or another may occur in the neighborhood of the stomach, producing bands of connected tissue which effectually prevent the evacuation of the stomach contents. Besides, there may be pressure of tumors of various kinds, especially of tumors in the neighborhood of the liver, which may close the pylorus. The obstruction may be in the duodenum, and this will prevent the emptying of the stomach. In a word, careful investigation of all the organs lying near the stomach must he made whenever there is stagnation of food, the cause of which is not easy to find.

Diagnosis of Stagnation.—The presence of stagnation of food may be suspected, as has been suggested before, from the eructation of food taken a considerable interval before it is tasted again. It has been said that if there is anything left in the stomach three hours after an Ewald test breakfast, then stagnation is present. Seven hours should be allowed after a meal for the complete emptying of the stomach. Perhaps the best way of all to decide the question is to examine the patient fasting in the morning, after a full meal has been eaten the night before, when, if the stomach is found empty, no serious stagnation of food exists. A complete examination of the patient should be made in order to determine the presence of affections of any other organs, especially in the neighborhood of the stomach. Systemic conditions, such as blood dyscrasiæ, and various intoxications, sometimes produce functional weakness of the stomach wall and consequent stagnation. This complete clinical investigation is very necessary for a diagnosis.

Treatment.—Mechanical methods of treatment sometimes prove of considerable service in lessening stagnation, and the stomach gradually recovers its tone. Rotation of the trunk in such a way as to assist in the emptying of the stomach is especially important in this matter, and massage is a valuable auxiliary. This must not be massage in general, however, but scientific manipulation of the abdominal wall in such a way as to aid in the passage of the stomach contents. In Dr. Stockton's hands the alternate hot and cold douche produces an active contraction of the stomach wall, and eventually leads to recovery of its tone. Needless to say, the general muscular condition of the patient is important in the matter, and care must be taken that properly directed exercise may help in the general tonicity of the muscular system. Drug treatment is not of so much importance as used to be thought, though there are many helpful remedies. In the milder cases particularly, and in order to prevent the development of more serious conditions, the proper use of carminatives and of bitter tonics will be found of special service. The diffusible stimulants must not be neglected, and will often help in restoring tone until a normal condition is re-developed. For an irritable pylorus it is not so much surgery that is needed, and especially not early in the case, but unstimulating food. In some cases under Dr. Stockton's care a moderate liquid diet, with careful selection of material, has improved patients that seemed to be almost hopelessly ill from irritation of the pylorus, and in whom it appeared to be inevitable that surgery would be needed.

Surgical Intervention.—The surgeon is not needed as often as it is thought in recent times, and it must be remembered that even ulcer of the pylorus, though it produces an ugly condition, may be cured effectually by medical treatment, and is as likely to stay cured as after the use of the knife. After all, it must always be borne in mind that where ulcer of the stomach has occurred once it is likely to recur, and a stomach that has been weakened by surgical intervention is even more likely than the ordinary organ to become the location of a subsequent ulcer. Gastro-enterostomy is often of great service in cases of ulcer of the stomach, but it must never be forgotten that such patients are not in as good condition as they were before, and are likely to suffer from many forms of digestive disturbance. All that the gastro-enterostomy accomplishes is to provide drainage of the stomach, and a natural drainage is always the best.

Surgery of Gastric Cancer.—In cases of stomach cancer, where there is no hope of complete removal of the growth, gastro-enterostomy may yet prove of distinct service. When serious stagnation of food is present nutrition is greatly interfered with, and indeed it is the condition of inanition in gastric cancer that makes the saddest part of these cases. This can be avoided to a great extent by gastro-enterostomy, which will often give those patients a year of comparative comfort and do away with the pains which have been so annoying before. Patients frequently gain in weight, and are able to take up their occupations, becoming quite encouraged. The operation should always be advised, even though a radical good result is not expected.

Lavage.—In certain conditions of dilatation of the stomach, especially with yeast and other fermentations, washing out of the stomach is a very effective means of getting rid of bothersome symptoms. These fermentations may often be lessened by the use of salicylic acid. A combination of lavage and salicylic treatment is especially effectual in many cases. At times the salicylic acid alone will produce results when patients have been suffering very severely.

The Stomach and Other Organs.—Dr. G. W. McCaskey, of Fort Wayne, Ind., in opening the discussion on stomach diseases, said that the stomach produces effects in many other organs, and that the presence of severe indigestion, especially if there is a combination of gastric and intestinal affections, may be reflected in nearly every organ of the body. In most cases the intestines are more directly at fault, but the stomach is not without its share of the blame. Where such disturbances exist the development of renal disease is not uncommon, and the nervous heart symptoms consequent upon stomach disease sometimes weaken that organ and predispose it to more serious affections.

Conservatism in Stomach Treatment.—Dr. McCaskey said that in the treatment of the stomach conservatism is most important, certainly as regards surgery there has been a swing of the pendulum too far toward the extreme of taking cases out of the hands of the physician at a time when they may frequently be benefited by ordinary remedial measures. Unfortunately there is a tendency to think that unless improvement follows treatment very soon there is little hope of eventual benefit. In no department

of theraputics is time a more important element than in the treatment of stomach diseases. Dr. McCaskey has not found cold douches beneficial in cases of stomach trouble, and cannot agree with the experience of others in this respect. In the matter of nutrition carbohydrates and hydrocarhons must be taken to correspond with the amount of exercise, or there will be disturbance of metabolic equilibrium.

Technic of Use of Stomach Tube.—Dr. Morris Manges, of New York, said that one great reason why the stomach tube is not used more frequently is that the technic of its employment is not properly understood. It is no wonder that many people fail to use the stomach tube to advantage, since they never employ the proper sort of a tube. Over and over again Dr. Manges has seen thin, very flexible tubes that of course could not be passed with any ease. Besides, many of the tubes supposed to be for the stomach consist of elaborate apparatus with bulbs and connections, so that considerable practice is needed for their use. All that is necessary is a moderately thick-walled tube, without any bulb, connected to a second piece of tubing by a glass tube of the same caliber, with a funnel at the end. With this the stomach contents can be obtained and examined without any difficulty. Many physicians display an awkwardness in its use that is the result of lack of practice. But after a certain amount of practice the examination of the gastric contents is simpler than the making of an urinary analysis.

Chemical Reaction.—It is more important to find the qualitative condition of the stomach contents than the quantitative chemism. At times only a very small quantity of stomach contents is available, and then test paper is all that is needed. This may be applied at the eye of the tube in the small quantity of material that is to be found there. Of course a single examination is absolutely useless. Several test breakfasts should at least be employed, and one test dinner. The fasting method, with examination in the early morning, is excellent for the determination of dilatation of the stomach or food stagnation. The gross look of a specimen of stomach contents is often helpful, for it shows the presence of mucus or the absence of proper digestion.

Mastication.—Dr. S. P. Black, of Pasadena, Cal., said that probably the most important single element in the treatment of stomach disease is the insistence on mastication. Undoubtedly after a demonstration with the stomach tube, such as Dr. Dock suggests, there will be less bolting of food. People eat too much, and especially too much of meats and the like, and these materials are found galore in the stools. After all, when thus evacuated, they only produce irritation without doing any good at all. When mastication is more complete the appetite is satisfied with less food, and the patient gets the benefit of all the food taken without expensive waste. No one can dictate in the amount of food taken, however, and even for the same individual the amount varies greatly at different times. Old men, evidently, do not need as much proteid material as young, and those living a sedentary life not so much as those exercising a great deal. Since the New Orleans meeting of the Association Dr. Black considers that there has been a very different realization on the part of the members of the Association of the true significance of chronic rheumatism. Undoubtedly many of the vague pains usually called chronic rheumatism are due to the absorption from the digestive tract of irritant materials improperly digested because the stomach has been overloaded as a consequence of insufficient mastication of food.

Blood Tests and Pepsin.—Dr. Miller, of Chicago, stated that blood tests are particularly of service in the examination of stomach contents, since even small amounts of blood point to the presence of beginning ulcers of the stomach, and it is in the initial stage that these can be treated to the best advantage. Even when hydrochloric acid is present it may be well to look for pepsin, and in its absence pepsin will often be found to be present and to be rather active. It is easier to find rennin than pepsin, and its presence shows that the digestive ferments are not absent. At times it is difficult to secure all the stomach contents, and then the Ewald aspirator is of special service. Dr. Miller considers that the presence of carcines or yeasts in abundance in the stomach contents furnish a definite proof that the gastric condition is benignant.

Overfeeding and Mastication.—Dr. J. M. Anders, of Philadelphia, said that there is no doubt that most people eat nearly twice as much as is necessary, and that their appetite would be considerably lessened if they chewed their food more and brought it more in contact with their palate. It is impossible yet to decide with any scientific accuracy what should be the variation of food amount for different ages and occupations. This is coming, however, with more definiteness than before. It is to be hoped that the presence of creatinin nitrogen will prove to be the index of proteid metabolism that has been suggested. It remains, however, for further investigators to confirm this finding. In the meantime, definite information can only be obtained by careful analysis of the food digested and the comparison with the excretion in both urine and feces. The influence of exercise, of baths and of sleep in various persons makes the problem much more complex than is usually thought.

Acute Stomach Rheumatism.—Dr. Anders considers that in certain cases of acute pains in the gastric region the proper diagnosis may be rheumatism or its complications. In a case of acute rheumatism, where the joint symptoms were in abeyance, pains occurred in the epigastrium, and only after careful investigation was it found that a dry pericarditis was found. Not infrequently the only subjective symptom of pericarditis is this form of painful stomach affection.

Fads in Eating.—Dr. F. G. Shattuck, of Boston, said that the history of the present movement as to the question of overeating has been of special interest to him because he has been brought personally in contact with some of those personally responsible for its beginning. Fletcher first took up the idea of mastication, lessening the appetite and consequently decreasing the danger of overeating. Afterward his son-in-law, Van Sommer, too up the idea and made some scientific contributions on the subject. Van Sommer used to be a rather stout and good-natured German until after he became Dr. Fletcher's son-in-law and took the new system. He has now become cadaverous-looking, but is satisfied that the new system is effectual in enabling him to maintain his metabolic equilibrium. Dr. Shattuck has dined with Fletcher and Van Sommer, and is rather interested in seeing them chew every portion taken into the mouth thirty times. Beyond this, however, the interest at table is not so noteworthy. While in Europe Dr. Shattuck had the opportunity to meet Dr. Sandrith, of London and Cairo. Dr. Sandrith is per-

haps the most distinguished physician for English visitors to Egypt. He says that he not infrequently has the opportunity to see patients who have been under Dr. Van Sommer's care at Venice, and that the main thing that he has to do with them is to encourage them to eat more, and so build them up to their normal condition of health. This whole question of the amount of food necessary for a given individual must be approached with the greatest care, and the experience of humanity in general is better than that of a few observers, or even of the most scientific investigation until after confirmation of the results by others and careful elimination of sources of error in the investigation. It is well known that the English soldier had to be fed the best, but was the bravest, and the English sailor needs far more food than any other laborer, but is the cheapest human instrument in the end.

False Gods in Surgery.—Dr. Shattuck considers, after listening to the discussion in the section on surgery, that there is much running after false gods. There are two conditions in which Dr. Shattuck believes surgical intervention may become really necessary. One of these is acute perforation, and the other is obstinate cicatricial contraction. Certainly for ordinary ulcer of the stomach the death-rate from operation is too high, and besides there is a liability to recurrence that makes surgical intervention inadvisable.

California Investigations.—Dr. Pond, of California, said that some work is being accomplished at the University of California that has attracted inconsiderable attention in America, but much attention abroad. A German investigator who recently visited California did not hesitate to say that it is the best work on problems of digestion now being accomplished anywhere. Though the investigations concern mainly human beings, they also touch upon animal digestion, and so have been published in the Bulletins of the Agricultural Department of the State.

Present Position of Stomach Diagnosis.—Dr. James J. Walsh, of New York, said that the present discussion on gastric disease is likely to be of as much value in clearing the decks for future advances in gastrology as the discussion on kidney diseases was in that department. If there is one department of medicine in which the old saying of Josh Billings has been especially exemplified, it is in the treatment of gastric disease.

Billings said: "It is not so much the ignorance of mankind that makes men ridiculous as the knowing so many things that ain't so." Certainly the number of things that has been known about digestion and indigestion that are not so are legion. More remedies come to the doctor's table and more literature is issued by manufacturing chemists of varied authenticity than with regard to any other class of diseases. Ferments of all kinds, gathered from all fruits and plants and vegetables of all the world, and vaunted as more specific the more distant their origin, have been manufactured and tried, and announced as cure-alls. As a matter of fact it is the chemistry of the stomach of which least is known and little can be done to supply digestive juices. Each individual is a law unto himself, and no one can dictate to anyone else what he or she shall or shall not eat. Pavlow's researches show that the stomach provides a special kind of gastric juice for each different kind of food. The psychic element is more important in the preparation of digestive juices than almost any other link of the chain of nervous, mental and mucous factors that enter into digestion.

Motility Versus Secretion.—The experience of recent years shows that the motility of the stomach is much more important than its secretion. There are any number of cases on record now in which the motility of the stomach remaining unimpaired, though there was serious secretory disturbance, health was very little interfered with. Many patients suffer from achylia gastrica, a condition in which there is no stomach digestion, yet have no digestive symptoms so long as the stomach remains capable of passing on the material to the intestines. In the cases of stomach cancer, in which large portions of the stomach or even the whole of that organ have been removed, digestion has improved immediately after the operation, and the patients have gained in weight, though living without a stomach. In cases in which serious interference with nutrition as a consequence of failure of stomach motility the surgeons do gastro-enterostomy, and the patient immediately improves in health. It is not good to be without a stomach, nor is the gastro-enterostomized patient equal to the normal individual, but the lessening of the importance of stomach motility is emphasized.

Gastric Symptoms.—In the treatment of gastric symptoms, then, it is important to remember, as a rule, that what is to be modified is not stomach secretion, but stomach motility. If the food will only be passed on properly the intestines will compensate for the stomach, and as nutrition improves the gastric disturbances will disappear as a rule. Many symptoms of gastric disease are really the result of non-gastric affections, the motility of the stomach being disturbed reflexly, and improvement will only occur after the removal of this cause. Many of the tonic bitters, and especially strychnine and related substances, do good much more by acting on the gastric muscle than on the gastric mucous membrane. The stomach cannot pass on food if it is not properly masticated, or if it is too large in quantity. The advice to patients must be, then, mastication and mastication, and again, mastication. The lessening of the amount, especially of the proteid material, is evidently needed in many cases, though it seems not unlikely that the pendulum will swing too far in this matter, and the patients take too little rather than too much food. Above all others stomach patients must be considered as individuals.

Lessening of Fluid.—Dr. Lichty, of Pittsburg, said that by advising patients to masticate more, and to take less fluid during meals and for an hour afterward, many gastric symptoms disappear. Formerly he used lavage, massage and electricity, and found that the improvement that came in this way could be secured by advice with regard to mastication and lessening of the amount of food taken. Coarse food may by its continuous irritation produce hypertrophy of the pylorus. On the other hand, the tonicity of the stomach is increased by proper mastication. The surgeon has a very definite place in the treatment of stomach disease, and while at the present moment there is as much objection to his interference with what used to be considered medical cases, the physician will come to accord him a definite place here. Not infrequently stagnation of food is due to the presence of bands of adhesion. This can only be definitely diagnosed by means of exploratory operation, and no amount of treatment of any kind will give relief without surgical intervention. Dr. Lichty

considers that the examination of the vomit of pregnant women and children by means of test papers, especially litmus and congo, may give valuable information without the necessity for the use of the stomach tube.

Mastication and Limitation of Diet.—Dr. Cooper, of San Francisco, said that if patients only chew their food enough there is no need to dictate a limitation of diet. There will come naturally a limitation satisfactory alike to patient and physician. On the Pacific Coast particularly it is important to remember that in cases of aneurism the introduction of the stomach tube is contraindicated. Dr. Cooper has recently seen five cases of abdominal aneurism, in all of which there were marked stomach symptoms. There should always be a full clinical examination of the patient before the chemical examination of the stomach contents. Dr. Cooper has found that in cases where the introduction of the stomach tube causes great discomfort the use of a strong peppermint tablet five minutes before the introduction has an anesthetic effect that makes it more comfortable for the patient.

Absorption Not from Stomach.—Dr. Bridges, of Los Angeles, said that there was one physiological fact with regard to the stomach omitted from the discussion. This is that the stomach is not useful for absorption, hence the significance of its motor power. The stomach is meant mainly as a reservoir, so that food may be taken at reasonably long intervals and properly mixed here. Even water is not absorbed from the stomach, and the organ is a convenience, but not a necessity. It is important, however, to decrease the useless labor put upon the stomach, especially in crushing the food not masticated. It is not true that the stomach produced directly other diseases, but is itself much influenced by all other organic affections.

Proteids After Adult Life.—Dr. Frank Billings, of Chicago, in closing the discussion, said that it is hard to decide just how much proteid must be taken, but only enough is needed to make up for body waste. Carbohydrates and fats supply the fuel for its energy. It is interesting to know that Fletcher and Van Sommer are relatives in law, and it is possible that their sacrifices in so good a cause may prove for the benefit of humanity. Undoubtedly too much proteids are consumed under the present dietaries, and a reaction in the opposite direction will do good. Dr. Billings wished to remind investigators of gastric contents that whenever bread is employed in the test meal, even though it be two days, yeast cells are sure to be found in the stomach contents when removed. They may be thought to be abnormal or to have some significance, but they have not.

Gastric Mucus.—Dr. Dock, in closing the discussion, said that practically any mucus visible in the stomach contents is abnormal. The examiner must, however, be sure that the mucus does not come from the mouth or the respiratory passages, or from mechanical irritation of the mucous membrane of the stomach, owing to awkwardness in the manipulation of the stomach tube. Dr. Dock considers that test papers are good in the analysis of stomach contents, but should be controlled by the burette, and the original practice in chemical investigation of the stomach should be made with the burette for proper discipline. The vomit of patients will not replace the stomach tube, and even when material is vomited there may still remain a considerable amount in the stomach of quite different material. When sarcines are present in large quantities, then the condition is not malignant. Yeasts do occasionally occur in cancer. Dr. Dock is sorry that he cannot agree with Dr. Walsh in considering that the shutting off of the stomach so as to allow the passage of contents is at all an answer to gastric difficulties. After gastro-enterostomy occasionally peptic ulcers occur, and the last condition is worse than the former. There is a middle ground of surgery and nihilism in gastric therapeutics in which very encouraging results may be obtained.

Non-Gastric Disease Percentage.—Dr. Musser, of Philadelphia, said that 65 per cent. of stomach disease is secondary to affections in some other parts of the body. More than 10 per cent. of these cases at least present none but stomach symptoms, and at the beginning of obscure affections of other organs there is still a larger proportion of obscure gastric symptoms. Practically any organic disease in the body may produce secondary gastric conditions, and nearly all of them do eventually.

Mastication Most Important.—Dr. Stockton, of Buffalo, in closing the discussion, said that there is a proneness in the present day to say that organs are not necessary. To some extent it is true the stomach function may be eliminated without very serious results. Nature sometimes produces a condition of achylia gastrica in which there is no stomach digestion, and an increase of motility hurries the food on into the intestines, to be digested there. Dr. Stockton has not, however, ever seen a case of achylia gastrica in which the patient was well. They come to the physician not complaining so much of stomach symptoms as of nervous conditions of various kinds, lassitude, lack of energy, and nervous depression. Anemia is a common result of this lack of stomach digestion. The physician must then, by his advice with regard to mastication and a lessening of the amount of food taken, secure stomach motility and the prevention of interference with it as far as possible as well as taking care of stomach secretions.

Dr. Billings, in closing the discussion, said that there were three books that he should like to recommend all the members of the American Medical Association to read, the reading of which he was sure would give them more practical information than any other he could name. They are: "The Physiological Economy of Nutrition," by Prof. Chittenden, of Yale University; Dr. Follin's articles on "The Physiology of Digestion," which appeared in the *Journal of Physiology* for the first three months of the present year, and Prof. Pavlow's book on the "Physiology of the Digestive Glands," which, written originally in Russian, has been translated, and is the most valuable contribution to gastric physiology made in recent times.

Dr. W. D. Brydone-Jack, of Vancouver, the President of the British Columbia Medical Association, asked to be allowed to invite the members of the American Medical Association to stop off on their way home, and attend the sessions of this Canadian Medical Society, which will be held on Tuesday and Wednesday, July 18 and 19, that is, in the week following the meeting of the American Medical Association.

Coccidioidal Granuloma.—Dr. W. Ophüls, of San Francisco, discussed the gross morbid appearances of this disease, of which only a few cases were known a few years ago, but which is now recognized as occurring not uncommonly. At first it was thought

to be due to a protozoon; then its etiology was attributed to a coccidium. After a time, however, it was found that cultures of the micro-organism could be made, and that it grew not unlike a mould. As this is called oidium, Dr. Ophüls has considered that the name coccidioidal would be especially suitable. The symptoms produced and the pathological lesions are not unlike those produced by blastomycetes. The disease is, however, quite distinct from blastomycosis.

Discussion of New Cases.—So far some ten cases of the disease have been reported, and to these Dr. Ophüls adds three new ones. One of these was suspected to be malaria, a second was for years thought to be chronic meningitis of tuberculous origin, and the specimens were exhibited as characteristic of tuberculous inflammation of the meninges. Years after the death of the patient the parasites were discovered in the tissues. Another case was caseous, osteomyelitis, a fourth case was caries of the elbow in a Chinaman diagnosed as tuberculosis. It is evident that the affection can only be recognized by means of a microscope. It presents a great variety of lesions usually bearing a striking similarity to those of tuberculosis in its manifold manifestations.

Pathological Conditions.—It is an infectious granuloma, and its lesions bear a striking resemblance to most of the other infectious granulomata that makes its diagnosis extremely difficult. It produces small and large chronic abscesses, and its cutaneous lesions resemble those of glanders. It is probable that the skin manifestations are primary, and that from this as a focus of infection the disease becomes generalized at the end. A characteristic of the disease in the lungs is that it is not limited to these structures, but extends by continuity into the mediastinum or into the soft tissues of the neck. Whenever it finds its way into the blood current miliary coccidiosis occurs. The generalization resembles that of tuberculosis very much. The bones are very often infected and caseation of the adrenals is not uncommon. In animals experimented upon, especially guinea-pigs, the envolvement of the genitalia is frequently seen. This resembles the corresponding lesions in glanders more than anything else.

Frequency of Disease.—Dr. Ryfkögel, of San Francisco, said that this affection is evidently more common than has been thought. Its skin lesions especially have been mistaken for other and supposedly more benign affections. This is especially true in regard to eczema and various forms of tuberculosis of the skin. Various attempts were made to inoculate the disease into animals without success, as a diagnostic measure and for purposes of investigation, until it was found that not infrequently the micro-organisms were enclosed in tough fibrous tissue from which they could not readily escape. Even when intravenously injected the injection was unsucessful. The intraperitoneal injection succeeded, however. After the tissues were ground up in a mortar, so as to free the micro-organisms, then infection took place more regularly.

Thyroid Disease in California.—Dr. Herbert C. Moffitt, of San Francisco, said that thyroid affections were more frequent in California than had been thought. The presence of aneurisms and of arteriosclerosis are certainly more common in California than in other parts of the country, and something of the same thing seems to be true with regard to thyroid. Endemic goiter is perhaps not as common as in Washington and the northern part of the Pacific Coast, where in certain of the valleys even animals are reported as suffering from enlarged thyroids. The tradition as to the occurrence of cretinism in California has been denied. Moderate enlargements of the thyroid are quite common, however. Five per cent. of young women entering the University of California suffer from some enlargement of the thyroid. Goiter is said to be less common in Southern California, and yet the statistics of the High School show 8 per cent. of the affection. In the interior the population is less affected.

Exophthalmic Goiter.—This disease occurs quite commonly and in two forms, in one of which the sexual and mental symptoms are more predominant than the nervous symptoms. It has been recently claimed that when the parathyroids are affected the sexual and mental systems are apt to suffer more. Not infrequently exophthalmic goiter eventually develops into a form of disease in which there is a lack of secretion of the thyroid, and in which fat pads may be noted above the clavicles and in the back of the cervical regions. In advanced cases there is a bib-like pad over the sternum and an apron over the abdomen. Many of these patients suffer from the dry skin, the pains in the joints, thinness of hair and lack of strength, which characterizes myxedema.

Iodine and Its Compounds.—Iodine certainly has an important relationship to the thyroid secretion. The abuse of potassium iodide in cases where there is already excess of thyroid secretion is sure to do harm. Kocher, of Berne, who has studied this class of cases very fully, considers that many of the thin, nervous people who jump at every sound have an excess of thyroid secretion, while phlegmatic people have a deficiency. In these cases it is necessary to to be particularly careful in the use of potassium iodine. Kocher has found over and over again that the use of this drug emphasizes symptoms already present, or brings them to notice when they have scarcely at all existed before. The most important early symptom is the fixed stare or glare so characteristic of exophthalmos. Care must be exercised, however, in studying this. Among the Southern nations who are accustomed to use their eyes much in talking, who, as it were, gesticulate with their eye muscles, a much better command of the eye is the rule than in other persons. They can look unwinkingly for long periods, and give one the idea that the Stellwag symptom is present. With regard to their rapid heart, it must always be remembered that certain nervous affections may produce it. Dr. Moffitt has seen it, for instance, in growing boys who indulged to considerable extent in masturbation. An excessive use of tobacco in boys will also produce the same sort of nervous cast heart.

Potassium Iodide in Diagnosis.—It should be remembered that potassium iodide will aggravate the symptoms of Graves' disease, and this may in doubtful cases be used for diagnostic purposes. It emphasizes the necessity, however, for great care in the use of iodine preparations and of thyroid extract in these cases. It very seldom happens, however, that a patient suffering from Graves' disease comes without giving the history that at some time they have been treated by thyroid extract. The unpleasant symptoms pronounced by the iodine preparations, and especially by potassium iodide, may be relieved by Fowler's solution, which acts not alone upon the cutaneous lesions, but also upon other manifestations.

Treatment.—For the nervous symptoms the bromides are the best. Phosphate of soda will be found of use, because it helps to alleviate the intestinal symptoms, while the bromides control the heart and restlessness. Parathyroid extract has been recently recommended, but does not seem to be of much service. Horsley suggested division of the isthmus of the thyroid as a surgical procedure, and obtained good results from it. Other surgical measures, such as removal of portions of the thyroid, have produced good effects in severe cases where complications were to be feared. Dr. Moffitt has employed rodagen during the last few months, and has obtained some good results. One patient has taken the remedy for eighteen months, six grains daily, and it has apparently controlled the pulse and other symptoms. One patient has taken the remedy for five months in similar dose, and is much better. A more pronounced case has taken it for four months, but without effect. Its employment in many further cases is needed in order to determine its absolute value.

Parathyroid in Graves' Disease.—Dr. James J. Walsh, of New York, said that as the result of Dr. McCallum's studies in Baltimore, and Prof. Gleys' investigations, witnessed in Paris years ago, he had been tempted to use parathyroid extract in some cases. Altogether four cases have been treated in this way, two of them apparently with good results, and two with a deterioration of their symptoms, possibly due to the parathyroid material they were taking. The two first cases were mild and of the kind in which suggestion plays a large rôle in the treatment, and in which intermission of symptoms are not unusual. The cases unimproved were of the severer type in older persons not much influenced by suggestion and usually without intermissions.

Graves' Disease in Old and Young.—As a matter of fact, under twenty-five years of age the symptoms of Graves' disease not infrequently disappear, sometimes to be absent for a long period, after very little treatment. In older cases of Graves' disease, however, intermissions are much rarer, and it is on these cases particularly that new remedies must be tried. In young persons the prognosis is not unfavorable unless acute complications threaten, such as interference with breathing or conjunctivitis as the result of exposure of the eye. In one case a very severe type seen when the patient was sixteen to eighteen years of age, complete remission of symptoms took place after treatment of the intestinal tract, and ten years afterward, though the patient had had in the meantime two children, there has been no return of symptoms.

Avoidance of Thyroid Extract.—Dr. Wells, of Chicago, said that he has, during the last twenty years, seen many cases of Graves' disease, and in very few of them has he not found on careful inquiry a history of thyroid extract being given as a remedy for the disease. Without exception, all of these patients have been made worse during the time they took the thyroid extract, and it is evident that a warning is needed in order to keep practitioners of medicine from experimenting with this harmful substance. In Dr. Wells' own experience codeine has been the most useful drug for the control of the nervous symptoms, and its use may be prolonged almost indefinitely. During the experience of the last few years particularly this has proved an excellent remedy.

X-Rays for Graves' Disease.—Dr. Firmly, of Tacoma, Wash., said that in a certain number of cases of Graves' disease treated by X-rays he has obtained improvement by exposures to the X-rays. Cases that do not yield to other remedies seem to do very well under this. Out of six cases only one failed to be benefited.

Spontaneous Fluctuation.—Dr. McCaskey, of Indiana, said that spontaneous fluctuations of the symptoms of Graves' disease are so common that it is difficult to decide whether a remedy is helpful or not. Intermissions occur, but after a time the symptoms recur. His experience with operative treatment has not been very favorable, though in some cases improvement has occurred a considerable time after the operation.

Dr. Whiteside, of Portland, said that quite a few dogs in the neighborhood of Portland suffer from enlarged thyroids. These have a more rapid pulse than other animals of the same species, but do not suffer from prominence of the eyes.

Frequency of Enlarged Thyroid.—Dr. Grandee, of Norfolk, Va., said that there are more enlarged thyroids in nature than has been thought. In his own small practice he has seen many of them. Whenever the thyroid is increased in size patients are nervous and have a tendency to rapid pulse even though there may be no definite symptoms of Graves' disease. When the thyroid secretion is decreased patients are inclined to be fat and have a slow pulse. These need thyroid extract, while the thin, nervous person is always harmed by it.

Incomplete Graves' Disease.—Dr. Lichty, of Pittsburg, agreed with Dr. Grandee as to the frequency of Graves' disease, and added that in no disease is early diagnosis so important as in this affection. If any two of the cardinal symptoms are present, then the diagnosis of Graves' disease should be considered justified. Besides the rapid heart, the enlarged thyroid, and the prominent eyes, Dr. Lichty considers that tremor and increased perspiration should be considered as cardinal symptoms. Young women should be warned when such symptoms are present of the danger of skating, bicycling, gymnastic exercises, and other overexertion. Cures are obtained by means of the rest treatment, and where these fail the removal of a portion of thyroid is the best method.

Exophthalmic Goiter and Myxedema.—Dr. Moffitt said, in closing the discussion, that patients suffering from Graves' disease for many years slowly slip into myxedema. Treatment is not so hopeless in the old, in his experience, as has been said. When gastric symptoms are present these must be treated, and for the nervous symptoms the bromides and belladona are especially effective. Dr. Moffitt has found that in young women particularly operation gives excellent results very frequently, to his knowledge four out of five cases having distinctly improved, though the symptoms had been very severe.

Type of Tuberculosis on the North Pacific Coast.—Dr. Woods Hutchinson, of Portland, Ore., described a special type of pulmonary tuberculosis which seems to exist on the North Pacific Coast, especially in Oregon, Idaho, Washington and Montana. It has the following characteristics, which have been noted at the Washington State Sanitorium for Consumptives, not far from Portland. The sanitorium is not long open, and only 81 cases of tuberculosis have been under treatment; 36 of these have proved to be of this specially virulent type, and some 25 other cases, in private practice, of the same type, have been carefully studied. The most striking fea-

ture of the cases is the rapidity of their course. The most careful examination of the history fails to show any affection existing more than three to four months before they come under observation, and yet the patients are in the third stage of pulmonary tuberculosis. Besides this rapid course there is a very weak and rapid pulse, which sometimes cannot be detected at the wrists, and often cannot be counted there, but must be examined with the stethoscope over the heart itself.

Temperature.—Besides the high pulse the most characteristic feature is the temperature, which is not high, but is often markedly subnormal. Not infrequently a temperature of 94° or 95° F. in the morning will be found to occur, though the afternoon temperature is not much above 99°. In one case the early morning temperature was only 93° F., and the afternoon just normal. It seems not unlikely that some of these cases run their course with a permanently subnormal temperature.

Pulmonary Physical Signs.—The absence of physical signs is a noteworthy feature of the cases. There are very few râles, and no bronchial breathing at the beginning. There seems to be no disturbance of the percussion of note. After a time, however, familiarity with the cases shows the presence of a boardlike tympany that simulates the normal percussion sound. At the autopsy the lungs are found to be infiltrated on the surface without any special affection of the apices of the lungs. The anterior surface of the lungs is more affected than other portions. This thickening of the anterior surface sometimes gives rise to an apparent absence of air sounds, and makes the breathing distant. At the autopsy the lungs are hard to get out of the thorax, because, instead of being shrunken, they are enlarged and are found indented by the ribs. There is a marked absence of cavities.

General Symptoms.—Another feature is the absence of hemorrhage. Early in the case there is very little cough. For the first three months there is a little hacking in the morning that seems to be scarcely more than a catarrhal raising of superabundant mucus. The expectoration is slight, of glairy consistency and seldom contains tubercle bacilli. When the bacilli are found they have certain special characters of their own. They are short and thick, and resemble those seen in bovine infections. Dr. Ravenal, when consulted on the subject, ventured to suggest that the description of the bacilli associate them with this form of infection from animals, and as Washington and the other States are cattle-raising countries, the reason can readily be understood.

Etiology of This Type.—Dr. Hutchinson does not find that this special type is due either to the altitude or to the moisture of the places in which patients live. Some of them have come from along the Sound, where they have been living practically at the level of the sea, while others come from back in the Cascade range of mountains at rather high altitudes. Needless to say, these various altitudes present very different conditions of moisture. Race seems to have nothing to do with the development of the disease, though most of those affected are Americans of the second or third generations, who have been living in the Northwest for some time. It will be recalled that the Indians suffer very severely with tuberculosis—presenting a death rate of over 50 per cent., though they live in tents and have all the advantages apparently of the outdoor treatment by their natural habits of life. The Indians present no racial immunity to the disease, and it would seem as though the Northwesterners have lost their racial immunity, as the result of long living in the outdoor air.

Heart Weakness.—The subnormal temperature, the marked feature of the cases, seems to be due to the fact that the systems of these patients do not react sufficiently to produce a rise in temperature. The difficulty is the weakness of the circulation, consequent upon more or less heart failure. The heart is weak out of all proportion to the other organs. In all cases of pulmonary disease the prognosis depends more on the heart than it does on the lungs. This is especially noteworthy in pulmonary disease, but occurs also in tuberculosis, though it has not been taken sufficient account of. It is well known that a rapid pulse at the beginning of tuberculosis usually makes an unfavorable prognosis. In these cases the galloping heart which, as the disease advanced, became even embryonic in its sounds, giving the tic-tac or equality of sounds. The sound being nearly equal in length to the first, that in all affections makes an unfavorable prognosis.

Temperature Range.—Dr. Woods Hutchinson says that the important diagnostic lessons in these cases is the necessity for studying not alone the febrile temperature of the patient, but the whole daily temperature range. Sometimes it is said that unless a patient has a temperature of 99.5° F. that there is no fever. If, however, it will be found, as is not infrequently the case, that the morning temperature is below 97° F., or even lower, then anything above 99° F. in the afternoon indicates a serious interference with the average normal temperature. In fact, whenever the temperature range has a variation of more than one degree and a half in the twenty-four hours, there is some toxin being absorbed into the circulation which causes a disturbance of the daily normal temperature rhythm. In all cases of tuberculosis, then, careful observation should be made to determine the temperature range.

Acute Miliary Tuberculosis.—Dr. Cheney, of San Francisco, said that for ten years he has been carefully studying cases of tuberculosis as they occur in San Francisco, and he has not seen the type of tuberculosis suggested by Dr. Woods Hutchinson, so that it is not common at least along the Southern Pacific Coast. Acute miliary tuberculosis, as it occurs in San Francisco, resembles these cases described by Dr. Hutchinson not a little, but it does not occur near so frequently as described by Dr. Hutchinson. After all, it must not be forgotten that considerably more than one-third of his cases are of this rapidly progressive type.

Dr. Miller, of Chicago, suggested the possibility of secondary infection in the specimen presented by Dr. Hutchinson.

Hasty Consumption.—Dr. Norman Bridges, of Los Angeles, said that the cases described by Dr. Woods Hutchinson in their rapid development resembled very closely the cases of miliary tuberculosis that used to be called hasty consumption, Phthisis Florida of the old text-books. In these cases the temperature is frequently not high at any time. There is not very much expectoration, and the breaking down in the lungs is not nearly so prominent as in other forms of consumption. What needs explanation, however, is the frequency with which these cases occur in the Pacific Northwest. The physical signs, too, are usually more prominent than suggested by Dr. Hutchinson. There are always minute crepitant

râles resembling the crepitant râles of pneumonia. Their presence is due to the rapid infection of the surface of the lungs which causes a correspondingly rapid consolidation. Death takes place in from a few weeks to a few months.

Race Susceptibility.—Dr. Brown, of San Francisco, said that the description of Dr. Hutchinson's cases vividly recalled the progress of tuberculosis as it is seen in especially susceptible races. The case of the Indians has already been suggested. The Chinese are another race that prove very susceptible to this disease, and in whom it runs a very rapid course. This would seem to be due partly to the absence of proper habits of life among the Chinese, and a lack of the nutrition suitable for our climate. The pathological specimen presented by Dr. Hutchinson resembles not a little the conditions seen in monkeys that have developed tuberculosis. Not a few of the soldiers returning from the East brought monkeys with them, and many of these succumbed eventually to tuberculosis. At autopsy they presented lesions not unlike those of acute miliary tuberculosis of human beings, and like those described by Dr. Hutchinson and seen in the specimens.

Secondary Tuberculosis.—Dr. Ophüls, of San Francisco, said that the lungs presented by Dr. Woods Hutchinson constituted a very rare specimen. They resembled more the lungs of pearly disease of cattle than tuberculosis in human beings. The most notable characteristic is the almost complete absence of cavities, notwithstanding the advanced tuberculosis process. In cattle, too, there is always considerable calcification of the nodules of tuberculosis, absent here. Dr. Ophüls has never seen a tuberculosis lung like this either in Europe or in America. Certainly they do not occur in California. It seems likely that this case is an example not of primary tuberculosis, but of a secondary process consequent upon a primary focus somewhere else in the body.

Dr. Mackay, of Oregon, said that the disease described by Dr. Hutchinson resembles miliary tuberculosis, though of course it may be an unusual type, possibly of bovine origin.

Dr. Moffitt said that this type of tuberculosis resembled somewhat the pneumonic phthisis seen in the susceptible, and occurring among the Chinese. Even this, however, is much rarer than the affection described by Dr. Hutchinson, and has certain distinct differences.

Primary Kidney Tuberculosis.—Dr. Woods Hutchinson, in closing the discussion, said that in the case from which the specimen was presented the primary lesion had been in the kidney. The symptoms presented by the kidney tuberculosis were so acute that an operation was performed for stone in the kidneys. At the operation the true condition was discovered, but after three months the patient died with the lesions shown at autopsy. Undoubtedly the case resembles cases of tuberculosis in animals more than in human beings. In some experience at making autopsies at the London Zoo corresponding lesions were seen. In the Indian reservations this same type occurs very frequently. It would seem then that susceptibility had nothing to do with the virulence of the infective process.

Value of Various Hemoglobin Instruments.—Dr. M. Howard Fussell, of Philadelphia, discussed the value of various hemoglobin instruments to the general practitioner of medicine. Fifty patients were taken unselected and studied by means of the Dare, the Fleischl and the Tallqvist scales. At least two observers used the same method of estimating the hemoglobin on each patient. As a result of this study it was found that the variation of the amount of hemoglobin present was very slight. The personal error amounts to at least as much as the instrumental error, but neither of them are sufficient to vitiate the conclusions that may be drawn from them. It is a comparatively easy matter to learn to use any of these instruments, and Dr. Fussell pointed out how significant is the knowledge that may be obtained from them. In all cases of anemia the recognition of the amount of hemoglobin present gives very definite information and indications for the employment or non-employment of iron therapy. This of itself would be sufficient to bring the instruments into much more general use than at present.

Officers.—The following officers for the medical section were elected for the ensuing year: President, Dr. Herbert C. Moffitt, of San Francisco; secretary, Dr. Miller, of Chicago. Dr. Dock, of Ann Arbor, was elected the representative of the section in the House of Delegates.

BOOK REVIEWS.

Diseases of the Heart and Aorta. By Thomas A. Satterthwaite, M.D., Professor of Medicine in the New York Post-Graduate Medical School; Consulting Physician to the Post-Graduate, Orthopedic and Babies' Hospitals; President of the Medical Association of the Greater City of New York. E. R. Pelton, New York.

From his full grade as a teacher and clinician Dr. Satterthwaite has realized the genuine need of a work upon this intricate and interesting subject which combines brevity, clearness and rationality with practical and modernness of thought.

Purposely he has restricted, so far as possible, the anatomy and surgery of the parts, dwelling chiefly upon physical diagnosis, symptomatology and treatment, to the latter of which he devotes particular attention, giving at some length the Manheim method, with American adaptations, fully illustrated.

Throughout the text he has inserted more than one hundred illustrative cases which are both useful and instructive.

The author faithfully maintains the scope to which he has restricted his efforts, and as a handy book it deserves to become popular.

The Medical Annual; a Year-book of Treatment and Practitioner's Index. Twenty-third Year. John Wright & Co., Bristol, England.

The contributors to the Medical Annual number some of the distinguished English medical men, besides some well-known Americans. There is no doubt that this work represents each year one of the best compilations of the progress of medicine that is on the market. It is especially rich in illustrations that illustrate, and in practical hints for therapeutics. It is rather curiously interesting to find under the head of the treatment of smallpox by red light, the fact that the Chinese have for many centuries treated smallpox patients in this way, but after all, many of our most satisfactory empiric remedies date back to the time when their origin was lost in the mists of tradition, and it is hard to understand just how they came into use. For a single volume annual we know of none better than this.

VOL. 87. NEW YORK, SATURDAY, AUGUST 12, 1905. No. 7.

ORIGINAL ARTICLES.

AN ANALYTICAL AND CLINICAL STUDY OF THIRTY CASES OF ECTOPIC PREGNANCY.

BY SAMUEL M. BRICKNER, A.M., M.D.,
OF NEW YORK;
ADJUNCT ATTENDING GYNECOLOGIST, MT. SINAI HOSPITAL.

IN the two years ending December 1, 1904, thirty cases of ectopic gestation were admitted to the first gynecological service of the Mt. Sinai Hospital. It has seemed worth while to review these cases critically in their clinical and diagnostic lights for the purpose of determining the relative value of the varying symptoms presented in this interesting condition.

Sterility.—All authors, except the most recent, agree that a certain period of sterility is coincident with, or favorable to, the development of an ectopic pregnancy. In more recent light, however, it seems more correct to ascribe the sterility often preceding an extra-uterine pregnancy to some uterine or tubal lesion which is itself, possibly, responsible for the abnormal pregnancy, *i.e.*, a severe endometritis, a retroversion, inflammatory disease of the appendages, etc. Another reason for the alleged sterility lies unquestionably in the methods used to prevent conception, which some patients have frankly avowed, failed in the present instance. It is impossible in the present paper to go into the question of the etiology of ectopic pregnancy. Miholitch[1] has made out a good case for an accessory lumen or lumina in the tube. Ballantyne[2] suggests that if the ovum be detained in the tube till the trophoblast, by which the ovum attaches itself to the uterine wall, be fully formed, or if this be formed prematurely, the ovum may effect a lodgment upon the tubal mucosa. It may be that we shall never know positively the source or sources of tubal pregnancy; but whether Webster[3] is right in his atavistic theory, or whether congenital or inflammatory conditions are at fault, the fact remains that in some cases we find absolutely no deviation from the normal, while in others we see, accompanying the abnormal pregnancy, the grossest pathological conditions which should, in themselves, make for sterility.

In the present series of cases, the longest period of sterility was eleven years, the shortest period since the preceding pregnancy, eight months. The average sterile period for the thirty cases was 3.40 years. Seven of the patients, or 23 per cent., had never before been pregnant, so that it is impossible, in their cases, to speak of any period of sterility. Four others had had spontaneous abortions only, the periods of sterility being respectively eight months, three and a half years, two years and six years. One of these had had two attacks of gonorrhea, and another had fever in the recovery from her first abortion, presumably from some inflammatory process.

From these figures, it is evident that previous sterility in cases of tubal pregnancy is certainly not dependent upon any one factor and that it is not necessarily a premise to extra-uterine gestation. But I would like to emphasize this point in this class of cases: That the *inaptitude to conception* when it does occur, *is probably the underlying cause of the ectopic pregnancy*, and that the tubal pregnancy, on the other hand, does not depend upon the sterility. In other words, the anamnesis of the patient should not mislead the physician because a period of relative sterility has been noted.

Para.—Of the thirty patients, seven had never been previously pregnant, and four others had aborted but had never gone to term. Twelve had had one child, six had given birth to two children, and one had had four, one five, and one eleven full-term births. One of the patients had been previously operated for tubal pregnancy on the other side and had never otherwise been pregnant. Two patients had had abortions before a final gravidity which went to term.

Age.—The oldest patient of the series was forty-one, the youngest twenty-one years of age, the average age of thirty being twenty-seven and nine-tenths years. I have appended as the briefest form of expression, the following table:

Age....	21	22	23	24	25	27	28	30	31	32	33	34	35	37	41
Cases..	1	2	5	2	1	4	1	4	1	1	1	4	1	1	1

Tube Involved.—Among the thirty cases there was one hematocele. The character of the operation for which (posterior vaginal section), did not permit a determination of which tube had been involved. Another case was an intramural pregnancy with the typical history of an ectopic pregnancy. Of the remaining twenty-eight, fourteen pregnancies were found on the right side and the same number on the left, a distribution so even that it is impossible to speak of a predilection for the condition to attack either side.

Dysmenorrhea.—In but twenty-three of the cases is any note made of the character of the usual menstruation. Of these, fourteen are said to have no pain with the menstrual flow and nine are given as having had painful menses. These figures have no especial significance except, possibly, to indicate that the fourteen patients, at least, were not suffering from any gross pathological changes in the pelvic organs.

1 Zeitsch. fur Geb. und Gynäkol., Vol. 49, p. 42.
2 Antenatal Pathology and Hygiene, "The Embryo," p. 618.
3 "Ectopic Pregnancy," 1895.

The Bleeding.—The subject of metrorrhagia has been carefully studied. In three of the cases the data are missing. In twenty-seven cases, the average length of time preceding admission at which the patient last menstruated was 7.24 weeks. The shortest time at which the regular period had taken place was two weeks prior to admission. This was a case of tubal abortion in which there had been no external bleeding whatever. Two patients had menstruated last as long as three months before applying for admission; in one of them a hematocele was found, in the other a hematosalpinx of the left side. Between these extremes, every variety of irregularity in menstruation is noted.

In every case but one there is a history of irregularity in the menstrual flow, and this point is of great importance in considering the history of patients suspected of being the bearers of a tubal pregnancy. The usual statement, crudely put, involves a skipping of the period at the regular time with some bleeding before the time for the arrival of the next regular period. The variations show the most widely different phases. Thus, in one case (No. 184[1], a tubal rupture), the last menses before admission had taken place seven weeks previously, and there had been no bleeding or spotting of any kind up to the hour of operation. The other extreme is seen in No. 186, a tubal abortion, in which there had been constant bleeding for eleven weeks prior to admission after an amenorrhea of two weeks. Between these two forms, every variety of hemorrhage can be found.

It must be noted, however, that profuse bleeding in ectopic pregnancy is a rarity, and that its presence may usually be regarded as a sign that the condition is rather one of interrupted uterine pregnancy. In our series but four patients reported their bleeding as profuse, and in none of these did it last more than two weeks out of five or six weeks of unusual hemorrhage. A further study of the cases reveals the fact that profuse bleeding is recorded only in cases of rupture of the tube or of hematocele, and it also appears that the bleeding became more profuse at the presumptive time of rupture or abortion.

Scant bleeding or spotting is the rule in the majority of cases of ectopic pregnancy, and a moderate metrorrhagia is also not infrequently noted. In our thirty cases, eight patients reported slight spotting, four profuse bleeding, eleven moderate hemorrhage and two no bleeding whatever. One patient (No. 183, ruptured tube one day before admission), had bled profusely only the day before her operation.

The question of intermittent or of constant bleeding has been carefully investigated. Of the thirty cases, there are notes of 26 on this point. Sixteen of the patients bled constantly for a certain length of time and the flow subsequently became intermittent. In ten cases, the bleeding was of an intermittent nature only. In the former series of sixteen, we find many varieties in the character of the flow, some bleeding a little every day, some bleeding constantly for a time, the flow later becoming intermittent, and others bleeding for a time with subsequent entire cessation of the flow. There is evidently, then, no type of vaginal bleeding in cases of ectopic pregnancy, the main element which marks it being its great irregularity.

The appended table shows clearly the type of bleeding in the twenty-six cases:

Case No.	Probable Duration of Pregnancy.	Period of Amenorrhea.	Type of Bleeding.
284	One month.	None.	Constant.
285	Two months.	One month.	Constant for one month.
276	One month.	One month.	Constant.
275	Five weeks.	One week.	Constant for one and one-half weeks.
274	Five weeks		Intermittent.
273	Eleven weeks.	Two weeks.	Constant for six weeks.
272	Two months.	Six weeks.	Constant for two weeks.
278	Six weeks.	Two weeks.	Constant.
279	Three weeks.	Six days.	Constant for six days.
280	Two and one-half months.	Nine weeks.	Constant for two days before admission.
281	Five weeks.	Seventeen days.	Intermittent.
282	Seven weeks.	Two weeks.	Constant for two weeks; amenorrhea for nineteen days, constant since.
178	Nine and one-half weeks.	Two weeks.	Constant for five weeks.
179	Eight weeks.	Six weeks.	Intermittent.
181	Two months.	Five weeks.	Constant for three weeks.
182	Two months.	One week.	Intermittent.
184	One month.	Two weeks.	Constant for two weeks.
185	Three months.	Two weeks.	Intermittent.
186	Three months.	Seven weeks.	Intermittent.
271	Two and one-half months.	Three weeks.	Intermittent.
269	Eight weeks.	Five weeks.	Constant for three weeks.
270	Six weeks.	Four weeks.	Intermittent.
187	One month.	Eleven days.	Constant five days, then intermittent.
189	Seven weeks.	Four weeks.	Constant for three weeks.
192	Seven weeks.	Four weeks.	Constant.
277	Seven weeks.	Four weeks.	Constant for two weeks.

In the preceding table the period of amenorrhea is given. This naturally varies with the length of the pregnancy but there are evidently other factors which come into play. The varyingly intense congestion of the uterine mucosa in different cases[1], accounts for the hemorrhage from this organ and for its appearance at different times in different cases. It is probable, too, that the casting off of the uterine decidua has some bearing on the metrorrhagia. In the present series of cases, the longest period of amenorrhea was nine weeks, the average for the thirty cases being 3.4 weeks. In one instance there was no amenorrhea at all, the flow starting at once upon the cessation of the menses.

Pain.—Next to irregular bleeding, the most characteristic symptom of ectopic pregnancy is pain of one character or another. The character of the pain varies considerably. Three of the patients described their pains as like those

1 The numbers refer to the gynecological cases for the year.

1 Cazeaux, Revue prat. d'obstetrique et de pediatrie, November, 1903.

of labor differentiating them sharply from the cramp-like pain sometimes seen in tubal pregnancy. It is likely that these labor pains are only the accompaniment of the expulsion of shreds of uterine decidua or of blood from the uterus, for all these patients added that their pains were followed or accompanied by the appearance of blood. In two of these cases there was found a ruptured tube, in one a tubal abortion.

Eight patients described their pains as sudden and sharp, localized, as it appeared, over the affected tube, and varying from two weeks to two days before admission in its appearance. Of these four presented ruptured tubes, two, tubal abortions, and one each a hematosalpinx and an unruptured tube.

Eleven patients complained of cramp-like pains in the abdomen. In some of the cases this was not sharply localized but extended over the entire abdomen or its lower part. In the greater number of instances, however, the cramps were referred to the region of the affected tube. Their intensity also varied, some patients complaining of intense pain, others averring that it was only uncomfortable. Of these eleven cases, five were found at operation to be hematosalpingitides, three were tubal ruptures, three were tubal abortions and one was an unruptured tube. The cramp-like pain is now generally and quite properly accredited to the effort of the tube to rid itself of its contained ovum, or if this has already escaped, of the clot remaining in its lumen.

Bearing-down pains were noted by four patients, two of them in cases of ruptured tubes, two in cases of tubal abortion. Of these one was an intraligamentous rupture with the development of a large mass, one was a hematocele, and the other two showed moderate amounts of blood in the general peritoneal cavity.One patient complained of pain only when sitting, which was relieved by lying down, and two patients had greater pain on walking than at other times, one of these (a patient with a ruptured tube), having noted a sense of fulness in the pelvis on standing and walking. But a single patient said she had no pain whatever, her tube being the seat of a hematoma.

There are, as will be seen, no typical or classical pains by which we can distinguish the various forms of ectopic gestation. In cases of hematoma and tubal abortion cramp-like pains appear to be more common, but they are seen also in other forms of extra-uterine pregnancy. It is unfortunate that we can find no differential points to distinguish the various types by clinical signs; the examining finger must after all remain the principal guide to accurate diagnosis.

Twelve patients stated the character of their pains as constant or intermittent, four saying they were continuous, and six intermittent, two having pain which varied in its intermittency, at times being constant. There seems to be no relation, however, between the lesion and the constancy or intermittent character of the pain.

There were frequent complaints of vomiting after the onset of pain, twelve patients emphasizing this fact. Of these six were the subjects of ruptured tubes, one of an unruptured tube, two each of a hematosalpinx and a tubal abortion, and one of an intramural pregnancy. Unquestionably this vomiting was of so-called reflex character, provoked often by the presence of blood in the general peritoneal cavity, all the patients but one having this condition present. It is likely, too, that the pelvic peritonitis which often accompanies ectopic pregnancy may account for the vomiting.

The following table shows clearly the relation of type of pain to the lesion found at operation:

	Labor Pains.	Sharp and Sudden Pain.	Cramplike Pain.	Bearing-Down Pain
Tubal Rupture.....	2	4	3	2
Tubal Abortion.....	1	2	2	2
Hematosalpinx		1	5	
Unruptured Tube....		1	1	

Symptoms of Pregnancy.—Six of our patients considered themselves pregnant at the time of their admission. They had reached this conclusion on account of their symptoms—the amenorrhea, nausea and vomiting, frequent urination and painful breasts.

It does not always follow that an ectopic pregnancy is necessarily accompanied by the usual recognized symptoms of intra-uterine pregnancy. Indeed these symptoms are often strikingly absent. I have carefully gone over the histories of these thirty patients, however, and find that whereas in seven no record at all is given, the remaining twenty-three showed some interesting facts. Thus, eleven of them suffered from nausea and vomiting, while five had no such phenomena. Three had noticed enlargements of the breasts but seven had not observed this, nor had any of the patients noted the darting signs so common in early pregnancy. Four complained of frequent urination whereas nine did not suffer from this annoyance.

A résumé of these figures shows quite plainly that while the phenomena of early pregnancy are not by any means incompatible with the presence of an ectopic pregnancy, they are absent more frequently than they are found: a history of pregnancy, on the other hand, does not militate against the diagnosis of a pregnancy located in the tube.

Pulse and Temperature.—In the cases of freshly ruptured tubal pregnancies, the pulse was naturally much accelerated. In three of the cases it was imperceptible at the wrist at the time of operation, but these patients all recovered, a demonstration of the oft-repeated observation that women stand the loss of blood well. In other cases, usually those of rupture, the pulse was often 120 or higher at the time of admission. Unless there has been considerable bleeding, however, there seems to be no especial tendency toward rapidity of the pulse in tubal pregnancy.

The temperature, on the other hand, is usually somewhat elevated. Eighteen of our thirty cases had temperatures above the normal before operation. Eight of the thirty patients were operated upon immediately after admission and their temperatures were therefore not taken. Fifteen of the eighteen who had elevated temperatures had blood in the general peritoneal cavity either from rupture of the tube or from tubal abortion. Their temperatures were as follows:

99-100°	100-101°	101-102°	104° Fahrenheit.
9	8	1	1 (Infected Hematocele).

It is plain, therefore, that omitting consideration of inflammatory conditions, the preoperative temperature in cases of tubal pregnancy is due to the presence of blood in the free peritoneal cavity. Although it is needless to consider the elements which cause a rise of temperature in the presence of a foreign body of any kind in the peritoneum, we know that blood and even salt solution will bring this about. It must not be forgotten, however, that, as mentioned above, a pelvic peritonitis of more or less severity is a usual complication of tubal pregnancy and this may serve too as a causative factor of the temperature.

The practical bearing of moderately elevated temperature in the differential diagnosis of tubal pregnancy, when infection of any kind can be excluded, is evident. A normal or ordinary uterine abortion with which this condition is most frequently confused, gives rise to no deviation of temperature. Given a history, then, suggestive of tubal pregnancy, with a moderate rise of temperature, the suspicion will be strengthened if the other essentials for the diagnosis are present.

Tenderness.—One point which has been brought out with great clearness in this study is that the mass which is felt next to the uterus in cases of tubal pregnancy is almost invariably tender. The text-books but barely mention this fact; indeed few of them speak of it at all.

We have found that tenderness on palpation is a very constant finding in all our cases of ectopic gestation. Among the thirty cases, a note is made in twenty-three of the result of the pelvic examination in this particular. In twenty-two of these, the record distinctly states that tenderness or sensitiveness was present over the mass adjacent to the uterus, in the great majority of cases exquisite tenderness being complained of. This was entirely independent of the character of the lesion present; it was found equally in cases of tubal abortion, of ruptured and unruptured tubes, and of hematoceles. The cause of this sensitiveness lies undoubtedly either in the compression of the distended tube or in the peritoneal adhesions so often present. Whatever its origin, it offers a practical diagnostic point taken in connection with a history suggestive of ectopic gestation.

Abdominal Rigidity.—Ectopic pregnancy seems to offer an exception to many intra-abdominal lesions in that the abdominal wall is not often rigid. Rigidity is noted in six of our cases, whereas, in five the abdominal wall was especially lax. In other words, the abdominal wall may or may not be rigid, but the absence or presence of rigidity has no diagnostic significance.

Previous Pelvic Disease.—In view of the widespread belief or, at least, frequent assertion, that inflammatory pelvic disease is a prominent factor in the causation of extrauterine pregnancy, I have carefully investigated the histories and operative findings in the thirty cases to ascertain the extent to which this held true. Two of the patients gave a history of fever following a former puerperium; in one of these a hyposalpinx was found opposite the affected tube, in the other the pelvic organs were normal. One patient only had had previous gonorrhea and another had been operated for pyosalpinx on the opposite side a year previously.

But one patient in the whole series presented a typical history of pelvic inflammation. She had had repeated abortions and after her third labor had suffered from a purulent endometritis. At the operation for her tubal pregnancy, there was found an intense pelvic peritonitis on the left side with an unruptured tubal pregnancy in the tube which ran over a large ovarian cyst. On the right side there was a smaller, adherent ovarian cyst. No other patients presented pelvic inflammations of any kind.

We have, then, but five patients, or 16 per cent., who gave any evidence of previous pelvic inflammatory processes.

Whatever may ultimately prove to be the etiological factor or factors of ectopic pregnancy, it is certainly evident that a previous gonorrhea or pelvic inflammation alone is not responsible for it. It seems rational to believe that not one but many elements enter into the causation of the condition. In one case it may be endometrial or pelvic inflammation, or a congenital or acquired tubal anomaly, while in another it may be atavistic or improper or premature nidation of the ovum; or the fault may even lie with the spermatozoa. We do not know and it is unwise and unscientific to allege that any one of the elements named, or other factors, are responsible for the many cases of ectopic pregnancy constantly coming under observation.

Conclusions.—1. Sterility does not necessarily precede the development of ectopic pregnancy. If it does exist, its cause is often the same as the cause of the abnormal pregnancy.

2. The main characteristic of the bleeding in ectopic gestation is its great irregularity, there being no type. As a general rule it is not profuse. It may be constant or intermittent, and its character or profuseness has no relation to the type of the lesion. A chilly feeling often accompanies the bleeding, and vomiting and nausea may accompany the first flow. The uterine flow has apparently no connection with the death of the fetus.

3. The pain in tubal pregnancy is usually localized over the site of the lesion. It has no definite character; it may be cramp-like over the affected tube, it may simulate labor pains, it may be sharp and sudden, or it may be of a bearing-down nature. The pain during a tubal abortion and that concomitant with the presence of a hematosalpinx is usually cramp-like.

4. The usual symptoms of pregnancy may be present. They are frequently absent but their absence does not militate against the possibility or probability of an ectopic pregnancy.

5. Tenderness on palpation of the mass adjacent to the uterus is of great diagnostic value when taken in connection with the history and the other pelvic findings.

6. A rise of temperature between 99° and 100° F., in the absence of signs of infection is worthy of consideration in the diagnosis.

7. The causative factors of tubal pregnancy are probably numerous. Not one element but many may bring about the connection in different instances. It is likely that atavistic tendencies, congenital or acquired anomalies, pelvic inflammations, ovarian and tubal disease, all play a rôle in individual cases; but none of these factors alone is sufficient to explain all cases.

8. We have as yet no definite data by which we can differentiate diagnostically between all the varieties of ectopic gestation. Occasionally this may be done, but it is impossible always to distinguish between an unruptured tube and a tubal mole. A hematocele and a freshly ruptured tube can almost always be differentiated from the other usual lesions.

The value of Werth's dictum to regard every unruptured tube in the light of a malignant neoplasm, has not diminished with the years.

136 West Eighty-fifth Street.

THE TREATMENT OF CHRONIC NASAL CATARRHS WITH SULPHUR.[1]

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

The chronic nasal catarrhs are encountered in the daily work of the general practitioner and by their persistence for years or through life are a constant factor in the consideration of individual health and comfort. Their frequency will not allow them to be disregarded or relegated to the hands of those especially skilled and experienced in their treatment, for were experts to devote all of their time and energy to the cure, the material would simply overwhelm the operators.

The chronic nasal catarrhs are often a sequel to other diseases, while they in their turn may beget still other and dangerous maladies. It therefore follows from the frequency of their occurrence as well as from the interconnection of other local and systematic diseases that the man in general practice is from necessity compelled not only to recognize these catarrhs, but also that they are a factor in producing other disturbances of health present and to come. In undertaking to cure some disease in the field of his own work his task may be incomplete or futile unless at the same time he is able to cure or ameliorate the persistent disturbance in the outer portion of the respiratory tract.

The specialistic treatment of the chronic nasal catarrhs requires knowledge, skill and the acquired technic of practice, not only in the application and variation of remedies but also in sundry surgical procedures for making occluded air passages pervious. These different manipulations must properly remain the domain of him who has fitted himself by constant application in the treatment of suitable and selected cases, yet when these are provided for, the multitude of milder, latent, indolent and apathetic subjects, is left without relief.

The nasal cavities are the great depot for the reception of any germ or spore of any nature which can be carried by the atmosphere. In health they may there be found in any individual who has exposed himself to their reception; although a deleterious action by their presence may never be apparent. If this be true of the state of health with normal membranes, glands and secretion, it demonstrates insusceptibility or immunity should the germ be virulent. In chronic nasal disease, however, where membranes are altered, or partly destroyed, with submucous tissues congested or inflamed and glandular structures no longer functionating, with altered, infected and decomposing secretion and incrustation, together with surfaces without drainage, with heat and moisture always existing, the vitality and multiplication of pathogenic bacteria cannot but be increased with whatever power of infection they may possess.

The chronic nasal catarrhs prey upon the thin and weak, the unresisting constitutions; and by their development they produce impoverished blood, debility and more extensive disease of the respiratory organs, as well as of the adjacent ones of special sense, leading also perhaps as many insist to dyspepsias and their complications.

The atrophic or end stage of nasal catarrhs is incurable, but a systematic treatment that conserves functions not completely destroyed, that mitigates and cures constant symptoms, that lessens the concomitant debility and restores the threatened general health, seems very desirable. As a remedy fulfilling these requirements, for common use, the writer recommends sulphur.

Sulphur, without which dermatology would be barren in its therapeutics, has since antiquity been a familiar substance in medicine. It is styptic, desiccant, astringent, germicide, parasiticide and insecticide. It has never received a complete or perfect study and its most important medicinal properties, never having been fully considered, have been simply overlooked. It is

[1] Read at the Annual Meeting of the American Therapeutic Society, Philadelphia, May 4, 1905.

sufficient, however, here to view this element as a non-poisonous tegumentary antiseptic and preservative. That it has peculiar powers of healing when locally used, and that, too, in specific inflammatory processes, can be readily demonstrated, for examples, in the diphtheritic angina of scarlet fever, in suppurative and necrotic processes, as phlegmon and carbuncle or in peculiar infections like erysipelas.

Of late years a plausible theory has been uttered that the curative activity of sulphur is much enhanced by having it prepared in the form of a soluble compound or body and by inference that its simple uncombined state is more or less inert. This is a fallacy, because sulphur not in solution is quite active in all forms of its intrinsic powers, and although the "soluble forms" are likewise medicinally energetic, yet they are more strongly irritating and objectionable in color and odor.

The best galenical preparation is the official sulphur præcipitatum U. S. P., a light, impalpable powder, which by sufflation may be widely diffused through space.

In treating the several forms of chronic nasal catarrh, it is the custom of the writer to have the patient seated with head erect and the mouth open. The anterior nasal cavity is exposed with a speculum, the tip of the nose elevated and the sulphur freely and thoroughly blown in with a strong powder blower. This has been properly done when the powder appears from mouth and opposite nostril and an irritative cough results. The treatment is repeated upon the other side. The posterior nasal space and nasopharnyx may also be treated directly by way of the floor of the nose or fauces. These procedures are not entrusted to the patient unless unusually attentive to his own case. They are made two or three times a week for a month and once a week for the next two months. The local sensations of sulphur are not unpleasant. Occasionally in women it sets up a conjunctival hyperemia when used too profusely or accidentally blown upon the face, and in some females nasal irritation and pain are complained of. Then it is best to use the treatment but once a week. Except these minor objections the writer has seen none but beneficial results. With this method a considerable number of cases have been cured and the results seem uniform. Success of course requires a suitable selection, those in which there is no other primary nasal disease, deflection, deformity or growth requiring surgical methods.

The subjects of chronic nasal catarrh have an anemic look. Blood examinations amply confirm this. It is most noticeable in the young, and one of the earliest recognizable effects of free sulphur insufflations is a pronounced improvement in the color of the skin. It is with certainty that one can predict this change after one or two treatments.

To specify the several nasal diseases and wherein and how the value of sulphur can be elicited it may be noted that in *simple chronic rhinitis,* hypertrophic stage, the nasal discharge is diminished, the mucopurulent and purulent exudate becomes clear and much less, the intermittent nasal occlusion ceases, the dull frontal headache is gone, the manner brightens, the itching of the nose, sneezing and cough abate. The diffusedly swollen deep red membrane diminishes in size and lightens in color. *Intumescent rhinitis* is relieved. In *hypertrophic rhinitis* the effects are fair. In *atrophic rhinitis* the treatment cannot give such results as in the earlier stage. In *phlegmonous rhinitis* (furunculosis) the disease is often aborted and much relief given the pain and feeling of weight in the nose. In *simple chronic nasopharyngitis* (American catarrh) without organic obstructions the fulness and postnasal dryness, the postnasal dropping and incrustration, the hawking, expectorating and vomiting cease. Scabs and fetor, purulent and bloody discharges vanish; frontal and occipital headache, hebetude of mind and disinclination for work are gone. *Hyperplastic nasopharyngitis* is improved. *Scrofulous rhinitis* can be much helped, arrested or cured and secondary tuberculous infection of the cervical lymphatic glands prevented; likewise the ocular apparatus, the corneal surface and the eyelids preserved from extension of infection. This one of the initial periods of tuberculosis must be combated like all others with hygienic and constitutional adjuvants.

The immediate effects of the sulphur are to check the purulent irritating nasal discharge, heal the excoriations, improve the patient's pale and languid looks and stop the sniffling, sneezing, crust formation and odor. In *epistaxis* from any cause this treatment is one of the best applicable. It should, however, be reinforced with a gauze nasal tampon for twenty-four hours. The nose bleeding common in spring in young people and in children and recurring every day or two succumbs promptly to sulphur alone. Sulphur does not cure acute nasal catarrh-coryza, or "catching cold," to which all victims of the chronic forms are characteristically prone. This, as is well understood, requires in all cases such general treatment as hardens and invigorates the system and increases the weight of the body. As has been said, however, in chronic disease not requiring surgical aid and with the mucous membrane not destroyed by atrophic degeneration, sulphur gives much and lasting relief from all the persistent symptoms that torment existence, and it is maintained that it is as valuable as it is simple. As sulphur possesses such marked powers to cure nasal catarrhs it naturally follows that it may be a useful postoperative dressing, particularly in the surgery of the nasal cavities. That this is so the writer has convinced himself repeatedly. It possesses as such all the good qualities and properties of a perfect dusting powder, not the least of all being its hemostatic action.

TREATMENT OF THE INDIVIDUAL CASE IN APPENDICITIS.[1]

BY CHARLES C. ALLISON, M.D.,

OF OMAHA, NEB.;

PROFESSOR OF SURGERY, CREIGHTON MEDICAL COLLEGE; SURGEON TO ST. JOSEPH'S HOSPITAL; TO THE PRESBYTERIAN AND THE WISE MEMORIAL HOSPITALS.

Last November Dr. Parker Syms wrote an article upon appendicitis (*Annals of Surgery*) based on an analysis of 219 cases, 75 of which were personally operated upon, whereas 144 were operated upon by his assistants. In his own series of 75 cases the mortality was 6.6 per cent., whereas in the 144 cases treated by his assistants the mortality is 14.5 per cent. In his discussion of this paper before the New York Surgical Society Dr. Lilienthal reported 455 cases operated upon at Mt. Sinai Hospital during the four preceding years with a mortality of 10 per cent. The doctor heartily endorsed the position taken by Dr. Syms, adding that "when the symptoms were evidently receding upon admission to the hospital, an operation was *occasionally* delayed from hour to hour; but the operation was *never postponed* in the hope that the symptoms might recede."

Dr. George D. Stewart said that in his work at Bellevue and St. Vincent hospitals he had followed the plan suggested by Dr. Syms.

Dr. Rogers made the remarkable statement that most of the surgeons of New York were, he thought, in close accord with these views which, to quote from Syms, are as follows: "There is only one thing to do when the diagnosis is made and that is, operate." The rule might be modified, though rarely, and the reason ascribed for this extraordinary position is that, "in acute inflammatory condition in the abdomen the only way to ascertain its extent and seriousness is by operation." These quotations are made because they are recent and because they come from a surgical society to which we must often look for mature reliable advice.

It has been a good many years since the surgeons of the western country, who do a good share of work, have followed a plan of treatment which has a mortality so high. A Chicago surgeon (Ochsner) reports a mortality of 2.2 per cent. in a series of 1,000 cases including a period of practically three years. Another western hospital, St. Mary's (Mayos), reports 512 cases during the preceding year with four deaths, a mortality of eight-tenths of one per cent. During the past twelve months we have operated upon 231 cases with two deaths, a mortality of less than one per cent. No case was lost without operation and no bad case was turned over to an assistant. In six of the cases, in which the patients lived outside of Omaha, a second trip had been made, the condition not warranting an operation at the time of our first visit. All recovered.

Further reports may be quoted, but we have sufficient data to show that there is a great difference in the mortality between the eastern and very radical but fortunately smaller wing of the surgical profession and the conservative, analytical methods which have had origin and greatest encouragement among the western surgeons. There is a difference also in their methods of treatment based, it must be, upon a different conception of the pathology having origin in the appendix. That this pathology is most variable should, we think, be generally understood.

At least, three major conditions practically determine the course and severity of a given attack: (*a*) The infectivity of the mycotic agent which predominates in the inflammatory outbreak; (*b*) the amount of leakage, that is to say, the extent of the contamination at an early age; (*c*) the anatomical location of the appendix. To be more specific, all agree that a streptococcic peritoneal infection is very dangerous, but assuming that the perforation has been early (before adhesions have substantially formed) and the amount of exudate has been great, we then face what the English have called a "peritoneal catastrophe." Add to this a perforation near the tip of the appendix which reaches near the under surface of the liver, or if transversely located, perforation occurring practically in the middle of the abdomen, and we then face a dangerous infection at a point where protective adhesions are meager and more tardily developed. In other words, deeply located central infections do not have the early aid of the omentum (a condition which makes this disease more hazardous during the extremes of age) nor the supplementary support of the parietal wall along the borders of the abdomen.

These major considerations, we believe, are generally accepted by experienced observers. The real cleavage in views seems to originate upon points which are important, but minor in character, that is to say, there is some honest difference of opinion (1) as to the amount of infection the peritoneum, intelligently aided, may safely bear; (2) as to the method, which supports the peritoneum in this emergency, (*a*) by limiting the infection process, (*b*) by surrounding it with a barrier which offers at least a reasonable period of truce.

In the argument of these questions certain academic principles, we think, must be admitted; *e.g.*, that *rest* applied to an inflamed edematous segment of bowel promises the same substantial aid toward limiting the inflammation and encouraging resolution that it gives to other organs under like conditions. The promptness with which adhesions occur is favored by rest, and all admit that their development is an element of safety.

Arresting the peristaltic wave from above, that is to say, stopping its recurrent momentum from being expended upon a comparatively fixed, inflamed, edematous, septic segment, ameliorates the inflammatory progress so essentially as to

[1] Read before the Nebraska State Medical Society.

change the whole course and severity of a given attack; in other words, withdrawing food and avoiding cathartics, emptying the lower bowel by the repeated use of normal salt or standard enemata, encourages a peristalsis with a mild, gentle *origin* at the inflammatory zone rather than a painful, inefficient and damaging wave which *terminates* there. Want of agreement or a lack of appreciation of these major and minor but basic principles determining the course and outcome of a septic inflammation involving the peritoneum, having the appendix as its origin, leads to an even greater and certainly more serious diversity of views concerning the treatment.

No intemperate reference should be made to our eastern colleagues; they have been the pioneers, they have taught us valuable lessons concerning the pathology of this disease and pointed out its dangers. We wish only to be permitted to acknowledge a still greater achievement on their part, viz., that of openly retreating from a position which brings them an admitted mortality of practically 10 per cent. and to accept a course of management which has a mortality of from one to two per cent. It is not the interval cases, nor an inflammation confined to the appendix, nor the management of a localized abscess, that admits of debate, but it is especially the management of the sharp, progressive attack, *most often seen during the second day* with symptoms becoming more obtrusive on the third and even on the fourth days, that has led to views so divergent and regrettably to discussions so acrimonious.

The proportion of cases in which the symptoms quickly become overwhelming is quite small, whereas the number of cases, however sharp they may seem at first, which respond to the plan of applying rest to the inflamed zone and yet encouraging the escape of flatus, is surprisingly large. The fact that a case seems to be growing worse at the end of the second day is not an argument in favor of prompt operation, nor on the third day, and this statement applies to the fourth and sometimes to succeeding days. There is no definite time at which the above treatment (withdraw all the food, the frequent use of normal salt in the rectum *slowly* given, supplemented by ice-bags, the standard, or the molasses and milk enemata) will succeed in bringing away flatus. It may require twenty-four or forty-eight to seventy-two hours. But this one observation may be accepted as fixed, viz., if gas does not escape in a severe attack *before* operation, peristalsis will practically never be established *after* operation.

With the escape of gas the left side of the abdomen becomes softer, the actual limitations of the inflammatory process becomes more palpable, the opportunities to reach a suppuration safely, either by the intra- or the extraperitoneal methods are greatly advanced. If the extraperitoneal method can be employed, drain the abscess and stop. If the intraperitoneal method must be used, the operation really consists in the intelligent use of gauze tampons and the control of the pus as it escapes from the slowly opened abscess. Brisk, careful sponging allows practically no contamination of even the small, exposed area of peritoneum.

There is a class of cases, which we believe to be small, in which the above management does not lead to a horizontal recession of symptoms. The abdomen especially remains rigid throughout. The other symptoms reach and remain at the danger line. There is in these cases, so far as the clinical evidences can be interpreted, a general peritonitis. Some gas may escape, but the left side of the abdomen remains hard. These cases require drainage of the peritoneal cavity for the purpose of relieving tension (pressure) and absorption, but they do not need sponging and irrigating or extended search for all the pus.

In our series of 231 cases, above mentioned, 71 were suppurative; of these four assumed the type known as acute, general, septic, peritonitis, with one death; the 216th in the list; the remaining death, the ninety-first, was an interval, but very adherent, case, which died from hematemesis, there being a history of gastric ulcer three years before.

DISEASES OF THE PANCREAS.[1]

BY O. M. LONGENECKER, M.D.,

OF ROSEDALE, KANSAS;

LECTURER ON MATERIA MEDICA AND THERAPEUTICS, KANSAS CITY MEDICAL COLLEGE, KANSAS CITY, MO.

The pancreas, the most secluded organ in the abdomen, has at last yielded up a part of the secrets of its hidden and one-time hopeless inflammations. A study of the new light shed upon its history is intensely interesting and important.

This organ is absolutely necessary to life and until lately has not been studied relatively to its importance. Its parts on the right extremity, are the head and the neck; the latter is due to the superior mesenteric artery and vein. On the left are the body and the tail. The pancreas is six inches long, two inches broad and a half an inch thick, weighing two to three ounces. The general structure is almost identical with the salivary glands. The development is from the duodenum opposite the liver; both ducts slide around until they are contiguous, drawing back a portion of the intestine to form the diverticulum of Vater; this pouch which is the common outlet of the ducts has a great power for evil, holding gall-stones and thereby forcing gall through the pancreatic duct, causing the havoc to be described later.

Paul Langerhans, in 1869, discovered groups of cells in the center of the lobules which stain differently from the remainder, called the islands of Langerhans. They produce an internal secretion similar to adrenalin, which enters the blood by way of the thoracic duct, its office ap-

[1] Read at Kansas State Medical Association, Wichita, May, 4, 1905.

parently is, after uniting with a muscle ferment, to reduce the sugar in the blood. The digestive ferments of the pancreatic juice are trypsin, acting on albumin, steapsin, acting on fats, amylopsin, reducing starches, milk curdling and sugar-splitting ferments. On the basis of physiology, histology, pathology and embryology, the pancreas represents an organ within an organ.

Diseases of the pancreas are frequently combined with diseases of neighboring organs; the disease having extended from these organs to the pancreas, or vice versa. For these reasons as well as others, the diagnosis is extremely difficult. Diseases of the pancreas may be divided clinically into acute, subacute and chronic. Acute pancreatitis has a very high mortality and runs a course of fearful rapidity. Its etiological factor is doubtless a gall-stone in the diverticulum of Vater, preventing escape into the intestine, and the contractions of the gall-bladder forcing gall into the pancreas. The fat-splitting ferment acting with threefold power in the presence of gall, together with the other ferments of the pancreatic juice, destroys portions of the organ with resulting hemorrhage and escape of pancreatic elements into neighboring tissues. Death is due to hemorrhage, absorption of toxins, and pressure on the solar plexus. The diagnosis is very difficult and may be confused with gall-stones, peritonitis, intussusception, intestinal obstruction, ulcers of the stomach and duodenum, and possibly appendicitis and extra-uterine pregnancy. The disease is characterized by sudden onset in a patient previously healthy; excruciating pain in the upper abdomen, occurring in paroxysms, aggravated by motion, point of greatest tenderness, one inch above the umbilicus, persistent vomiting and collapse. Later, constipation, distention of upper abdomen, slight jaundice, fat necrosis in abdominal cavity, glycosuria, rare in early course, as the islands of Langerhans are usually the last structures affected.

Intestinal obstruction is differentiated by greater distention of abdomen, peristaltic waves, can be felt, seen and heard, obstipation is absolute, vomiting becomes stercoraceous, lesion is lower in abdomen, collapse is delayed. Biliary colic is distinguished by pain on the right side radiating to the right shoulder; in pancreatitis pain is in the median line, radiating to the left.

Perforations of the stomach and duodenum usually have a characteristic history, liver dulness disappears from escape of gas, vomiting subsides, peritonitis develops rapidly.

Appendicits is eliminated by testing for tenderness at McBurney's point.

The secretions from an injured pancreas, when mixed with blood, are very toxic, and may so affect the peritoneum when in the cavity that death will result. It will be remembered that pancreatic disease with its attending pressure on the solar plexus, formed a part of the symptom-complex of President McKinley's case, and proved so puzzling to the attending staff, that some of them suggested that the bullet had been poisoned with the toxins of some bacteria, to insure fatal results. The following is a quotation from the report of H. R. Gaylord, on the autopsy: "The extensive necrosis of the pancreas would seem to be an important factor in the cause of death, although it has never been definitely shown how much destruction of this organ is necessary to produce death."

In hemorrhagic pancreatitis the demand for prompt operative procedure is as urgent as in fulminating appendicitis. The surgeon may reach the organ from the left, the right, above or below the stomach, or from the back through an incision in the left costovertebral angle. The two latter are the most successful for drainage. Early operation for drainage is necessary on account of the exudate. If no operation is attempted and the patient escapes immediate death, pancreatitis of a chronic form, retention cysts, purulent or gangrenous conditions are highly probable.

Wiessinger reports two cases diagnosed during laparotomy, from fat necrosis. Incision and drainage effected a permanent cure. This report is given one year after operation. Hones, in the *Lancet* of February 18, 1905, reports a case of acute hemorrhagic pancreatitis, recognized and operated upon successfully. The patient vomited, epigastrium was tender, with localized swelling, abdomen was distended, the pulse 128, temperature 96.2° F., peritoneal cavity contained three pints of bright red blood. There was fat necrosis in the lesser sac.

Chronic disease of the pancreas may develop from the acute; from purulent conditions or neoplasms in neighboring organs; by infection from the intestine, may result from general or local tuberculosis. Cultures of typhoid bacilli have been found in the organ following an attack of fever. It may result from excessive use of alcohol, developing with cirrhosis of the liver; at least 10 per cent. of the latter disease develop glycosuria. Gangrene of the legs is usually if not always accompanied by pancreatic lesions.

Several additional tests have been suggested for recognizing chronic pancreatitis. The presence of sugar in the urine shows its existence to be highly probable but not certain. Several feeding tests referring to obstruction of the duct, are as follows:

Pancreatic juice alone will digest the nuclei of muscle fibers; feed meat wafers and examine feces. Pancreatic juice only will break up salol; examine the urine for the end products of carbolic acid and salicylic acid. If this juice is absent fats will be found in the feces; examine stools. If the duct of Wirsung be obstructed, in 70 per cent. of cases the secondary duct of Santorini is incapable for various reasons of discharging much pancreatic juice.

Dieckhoff, who is a famous authority on the pancreas, reports the following 53 cases: Acute

pancreatitis, 5; chronic pancreatitis, 15 plus (4 of doubtful diagnosis); carcinoma, 4; degenerative atrophy, fatty degeneration and fatty tumors, 21; cysts, 4. Total 53.

Draper, of Boston, in 4,000 autopsies found 19 cases of pancreatic hemorrhage, in 10 of which no other cause of death could be found. That is to say, at least one death in each 400 is from a cause that most of us never attempted to recognize.

A study of diabetes is inseparable from a study of diseases of the pancreas. Cohnheim has shown that by grinding frozen pancreas and frozen muscle, and pressing in a powerful press, neither extract will dissolve sugar in the blood. But by mixing the two extracts the sugar is rapidly decomposed. Conclusion, the internal secretion of the islands of Langerhans circulates in the blood with sugar until the muscles are reached, where the action of a second ferment causes sugar to be oxidized, forming heat and energy just at the point where it is needed.

Not all diseases of the pancreas produce diabetes, and not all diabetes is produced by diseases of the pancreas. Diabetes may be caused by: (1) Claud Bernard's puncture of the floor of the fourth ventricle, and perhaps by other nerve lesions; (2) by administration of certain drugs; (3) deducing from Cohnheim's experiments, perhaps from muscle abnormalities; (4) the liver may cause an overproduction of glycogen.

Interacinar pancreatitis, which destroys the islands of Langerhans, causes diabetes. Interlobular pancreatitis may be far advanced, and yet not affect these islands and no diabetes appear.

Hansemann, in the Berlin Pathologic Institute, prepared the following report of 73 cases: Diabetes without diseases of pancreas, 8 cases; diabetes without any statement concerning pancreas, 6 cases; diabetes with diseases of pancreas, 40 cases; diseases of pancreas without diabetes, 19 cases. Total 73.

Of the 40 cases, 36 were simple atrophy, 3 were fibrous in duration, and 1 a complicated case.

Prophylaxis in pancreatic diseases, as far as known, is a short chapter. Limit the use of alcohol to avoid cirrhosis of liver and pancreatic disease; treat syphilis to avoid arterial sclerosis; above all, remove gall-stones without waiting for nature to pass them, and perhaps have the bile forced into the pancreas with fatal results.

Treatment.—Surgical treatment has given good results. When the head of the pancreas is distended, an opening into the gall-bladder, with drainage, has cured a series of cases with a mortality of only four per cent.; this seems to us a very indirect approach to the subject. Incision in the long axis of the organ, with drainage below the stomach, or through the left costovertebral angle, seems the most scientific treatment; the latter avoids entering the peritoneal cavity. We hope that the time has come when no surgeon on discovering fat necrosis in the abdominal cavity, will hesitate to drain the pancreas. These small white spots of necrosis, in the mesentery are sometimes mistaken for miliary tuberculosis and are caused by the fat-splitting ferment changing the fat into glycerin, which is absorbed, and fatty acids, which remain in the dead cells, and give them the peculiar appearance. Medical treatment is of little value. Pancreatic extract may be given to aid digestion: iron and mercury have been tried, but all efficient remedies yet remain to be discovered. They may be described in a sentence from Tennyson:

> "The fair new forms,
> That float about the threshold of an age,
> Like truths of science waiting to be caught."

MALARIAL HEMOGLOBINURIA.[1]

BY LORIN A. GREENE, M.D.,
OF GREENVILLE, FLA.

In this article the author makes no pretense of presenting any new or startling scientific discoveries, but intended simply to relate some few personal experiences with resultant deductions, in the hope that a discussion may be incited that may benefit those of us who have in the past, or may in the future, come in contact with this grave form of pernicious malaria.

The pathology of an ordinary tertian or quartian malarial infection, with its severe, yet rapid, cycle of development, is well understood by all, but in the pernicious forms of malaria the lesions are so varied and inconstant that some new clinical aspect presents itself in almost every case. The gross blood changes, as we all know, consist in a marked diminution of the red corpuscles and a diminution of the amount of hemoglobin even in those cells which do not contain parasites or their spores. There is, as a rule, a relative increase of the large mononuclear leucocytes.

In every estivo-autumnal infection, a few days after the initiatory symptoms appear blood examination reveals large numbers of the adult crescents. The exact nature of these bodies, until recently, was problematical. Recent research has shown that these bodies represent the highest development of the estivo-autumnal parasite, their peculiar function being the propagation of the species in a cycle outside the human body. It has long been a demonstrated fact that some of the more mature ameboid forms of the tertian and quartian parasites, and the crescentic form of the estivo-autumnal parasite, remain circulating in the blood without effort at segmentation.

However, if a fresh slide of this blood be taken and allowed to remain for a few minutes in a moist chamber certain phenomena occur which are not seen in a specimen examined immediately after its withdrawal. Some of the mature organisms liberate long flagella, which are actively motile and immediately enter other mature forms.

[1] Read before the Florida State Medical Society, at Jacksonville, Fla., April 19, 1905.

It has been observed in stained specimens that each flagellum contained some of the nuclear chromatin of its parent body, and that this chromatin in the flagellum united with the chromatin of the organism which was entered by the flagellum.

Under the same conditions the adult crescentic form pursues the same cycle, the male crescent giving off flagella, one of which in turn fertilizes a crescent slightly different in morphology, presumably a female crescent. This process is evidently sexual in nature, and as the phenomena have never been observed except in blood which has been for an interval withdrawn from the body, it is the natural conclusion that under ordinary circumstances fertilization takes place outside the human host. These conjectures have recently been verified and the process of fertilization and maturation has been demonstrated in the stomach of a mosquito, the genus *Anopheles*. After a patient with an estivo-autumnal infection is bitten by the mosquito, the parasites in the stomach of the insect undergo a complicated cycle of reproduction analogous to the one described as taking place in a fresh slide preparation, and the resulting spores or ameboid bodies are deposited in the salivary gland of the mosquitoes. Such an insect is then capable of transmitting to an uninfected person sporozoites sufficiently developed to require only a few hours for blood destruction to commence after their introduction. These spore forms enter the red cells immediately and may be distinguished from the ordinary ameboid forms by their oval outline and the abundance and coarseness of their pigment. After a few hours these forms disappear and a little later, when we have every clinical evidence of an estivo-autumnal infection, we may not be able to verify our diagnosis by the demonstration of the parasite or its spore. But we do find a general granular degeneration of red cells and a marked phagocytosis, which is an expression of nature's effort to dispose of free hemoglobin from cells that have been disintegrated by some powerful toxic agent from an apparently remote depot of infection.

Pathologically a hemoglobinuria is simply the presence of free hemoglobin in the urine, resulting from the disintegration of the red blood cells by the *Plasmodium malariæ* or some associated agent. In a number of cases that I have seen I have been firmly convinced that the agent which wrought such terrific destruction with the blood elements was not the parasite itself, but some toxin, the existence of which depended either on the assistance or presence of the *Plasmodium*. It has been observed by many on blood examination that granular degeneration of red cells unoccupied by parasites has been more marked than of those acting as a temporary host for a *Plasmodium*. The question might be asked why do we not have a hemoglobinuria as a symptom in every case of remittent malaria? While it is indisputable that we have a liberation of hemoglobin in every case, in the milder infections, or those of short duration, the free hemoglobin is converted by the relatively healthy liver into bilirubin. But in those cases of long duration or greater intensity the congested condition of the liver prevents that organ from performing its function, and the free hemoglobin is as a physiological necessity eliminated by the kidney.

In every discussion of this subject in which I have participated or been an auditor, the chief point of difference has been in regard to treatment. Some advocate the use of quinine exclusively, while others hold that quinine causes the hemoglobinuria and oppose its use in any case. In my own experience the use of quinine depends altogether on the stage of advancement of the case when seen by us.

We have shown in the paper that the estivo-autumnal parasite develops, but does not reproduce in the blood. We have also shown that the sporozoites leave the blood current early and that after they begin to disappear, and never before, do the hemoglobinuric symptoms appear. Therefore, knowing as we do the specific action of quinine on a blood-borne parasite, the immediate hypodermic injection of quinine is indicated when we find the spore forms in the blood or know from previous examination that they have not long since disappeared. Unfortunately we are often prevented from this procedure until the rapidly manufactured toxins are about to commence active blood disintegation, and then the appearance of hemoglobinuria immediately after the administration of quinine gives rise to the fallacy that the drug is the causative factor of the symptom. Therefore I would advocate the hypodermic use of quinine in every case of estivo-autumnal malaria before the appearance of hemoglobinuria. And after the first hemoglobinuric paroxysm, if the drug has not been previously administered, its administration is justifiable in the hope that some few spores may be retarded in development and the sources of the toxemia numerically diminished. But after a thorough cinchonization, if the hemoglobinuria continues, I fail to see the rationale of the continued use of quinine. After the disease has progressed thus far without any abatement of the symptom, we have a condition similar to many other systemic infections and should treat it accordingly.

It has been my practice to commence early with the hypodermic injection of bichloride of mercury and continue its use at indicated intervals throughout the attack. Although it is argued that stimulation of an engorged organ is bad therapeusis, nevertheless the powerful hepatic stimulation brought about by the use of bichloride of mercury is an imperative necessity. Calomel in large and oft-repeated doses is a valuable adjunct to treatment from an empirical standpoint, at least. It is necessary that

the excretory functions be maintained. The intravenous use of the normal saline solution has been most useful in my hands, and has in a number of instances brought about a reaction in patients almost moribund. The hyposulphite of soda in saturated solution has been highly recommended, but has in my experience proven of doubtful efficiency.

Thus, after the proper administration of quinine, the condition should be treated as any other condition where we have a systematic toxemia due to some localized lesion, viz., typhoid fever or lobar pneumonia. That is to say, our treatment should be directed along expectant lines maintaining stimulation and promoting elimination.

THE DOCTOR AND THE PUBLIC SCHOOL.[1] [2]

BY THEODORE TOEPEL, M.D.,
OF ATLANTA, GA.

THE purpose of this paper is mainly to call to the physician's attention the child and its environment during its school life from six to fourteen years. Though not every physican is a politician, yet his professional standing carries sufficient weight to influence public opinion. A great amount of good would result if doctors in general would interest themselves more in the child at school. I am sure they are just as capable of filling positions on Boards of Education as men of other professions, especially when one considers that in school matters the prime aim to be promoted is the child's physical and mental welfare.

If we take the child at six years of age, when he first enters school, and note the change of conditions which take place, we are astonished at the physical and mental changes occurring during this first year at school. A child is removed from the home surroundings, where he was accustomed to be natural in action and speech, where the little body had a chance to grow, where the mind could develop at will. This child of free play is now crowded into a room with fifty-nine others. He must learn to sit still in his desk, a limited space of two by three feet. He can move by command only, and talk only when he is asked. Is it not evident to every rational thinking physician that this change should be carefully and gradually made? Would it not be better to take these little folks at six, and put them into a large room devoid of desks, where there is better opportunity for free exercise? The establishment of kindergartens, with their preparatory course for the regular school work, should be more universal in the city schools of the South. The expense of equipping and maintaining these kindergartens is small, when measured by the great amount of good derived from them.

The curriculum, as it is now made up, is very heavy for grammar school children, and is very frequently the cause of physical retardation and nervous breakdown. Not only does the pupil suffer, but the teacher very seldom escapes the evil results of overwrought nerves in the attempt to accomplish all the work the curriculum calls for. The cry of alarm should be sounded by the whole medical world in opposition to this grinding system. Wisely thinking pedagogues have shown the way of ridding the curriculum of all that is merely theoretical, not practical and useful, and have pointed out what should be taught our school children. They have chosen those things which eventually are conducive to the betterment of the people physically, mentally and morally. These men, true educators, as it were, should have the loyal support of the physician, for he is the one man who sees the results of wise or unwise education, being the confidential counselor in many familes.

I take for granted that we are dealing with children of families where they were properly cared for. We shall find that, before the child was sent to school, he received his breakfast at 8 o'clock, a light lunch at 10 and a warm dinner at 12, or not later than 1 o'clock. Note the change after he has entered school. It is customary in the South to have one long session. That means the children must report at school at 8.15 A.M. and be dismissed at 2 P.M., with one-half hour recess. This gives five hours spent in the school-room. The child now has breakfast at 7 o'clock, he takes a cold lunch with him, which is eaten at 11 o'clock, leaves school at 2 in the afternoon, and, if he is fortunate in having a careful mother, he receives a little warmed-up food at 3 o'clock; otherwise, he waits for a warm meal at supper time. It is evident that the physical and mental development of children fed in this manner cannot be normal. It is convincing that the results of irregular feeding during three-fourths of the period of growth and development will manifest themselves sooner or later in some form of disease. Should not this question of proper feeding receive the attention of the physician? Would it not be better for pupils and teachers to have a warm meal at 12 o'clock, and at least an hour and a half for rest and recreation between sessions?

Unfavorable physical conditions are prone to foster contagious diseases, and the greatest care should be exercised, on account of the susceptibility of school children, not to expose them to such. Realizing the importance of this, many authorities have appointed regular visiting school physicians, whose duty it is to visit the schools daily, and examine all children whom the teacher has sent to his office in the school suspected of having any contagious disease. In New York an inspector must make his visits to the school assigned to him before 10 A.M. He first examines the children isolated by the Principal, and also the children who have been absent

1 Shaw's School Hygiene.
2 Read before the Georgia State Medical Society, Atlanta, Ga., April, 1905.

from school for a few days. Once a week he makes a routine inspection, consisting of a class to class examination of each child present. The children march by the inspector, pull down their own eyelids and open their mouths wide. Any one suspected of having any trouble is ordered to the inspector's office for a more thorough examination. By this method many unreported contagious diseases have been found. Defects of sight and hearing are systematically sought for once a year among all pupils. We know that the way to prevent disease is to teach the people the primary cause of it, and how to avoid contact with the causative agent. In the public schools the children should be taught more of the practical things that will be of use later in life, and less of the useless things, which they forget as soon as they leave school. Half an hour a week during a child's whole school period devoted to a good common sense talk on personal hygiene is of greater benefit to a child than all the memorizing of physiology as it is at present taught. Instead of putting literature into the hands of children on this subject, facts should be put into their heads.

The conclusions drawn from physiological investigations made in Europe and America into the distortion of the body, caused by the demands of school life, are startling in the extreme. Every condition should be eliminated which makes possible the acquiring of physical defects in school, as well as the accentuation of those defects which the child may have had before entering school. Improper chairs and desks, not conforming to the size of the body, must not be allowed in the room. I have seen children varying in height twenty-two inches seated at desks and in seats exactly the same in size.

A few words will be appropriate in connection with this paper as to the room and schoolhouse, where the child spends five hours daily for eight years. I will picture to you a standard school-room, as now required by many of the larger city school systems, and if any of the physicians present have received their primary instruction in a place with similar advantages they are fortunate. The school-room should be the unit to be considered first in planning a school building; it should not be a building cut up into school-rooms. A school-room must be so planned as to give to the pupils who are to occupy it what the laws of health demand. A standard school-room is thirty feet long, twenty-five feet wide, and thirteen feet high. Of the primary grades forty-eight pupils are seated in a room of this size, each pupil having fifteen square feet of floor space and a little more than 200 cubic feet of air space. In the grammar grades (fifth, sixth, seventh and eighth grades) forty pupils occupy a room of the same dimensions. Here every pupil has 18¾ square feet of floor space and 243¾ cubic feet of air space. The amount of glass surface to light the room well should be one-fourth of the floor space of the room, or 187 square feet, and there is an unanimity of opinion that the light should enter from the left. The color of the walls and ceilings should be of a greenish gray tint; the window-shades should be of the same color, but somewhat darker. Properly sloped desks, chairs with backs, both having some mechanical contrivance which will admit of their being raised and lowered to accommodate the difference in size in pupils and rapidity in growth, should be in every room. They should be placed in such a manner that the aisles run the long way in the room. Every child should have 30 cubic feet of fresh air every minute at a temperature of 70° F. The sanitary conditions of the school building should be the best that money can afford. There should be well-lighted closets, with the best plumbing; the floors in these places should be of hard asphalt. Special care should be exercised in regard to pure drinking water; the use of individual cups should be encouraged. Besides the daily cleaning of the school-house, the floors should be scrubbed twice a year; the walls and woodwork should be wiped and painted annually. Desks and seats are accumulators of dirt. They should be thoroughly cleaned with kerosene during vacation. Some of the progressive school boards of this country have instituted school baths like those of many European schools, the object being to teach cleanliness and physical exercise. The school buildings should be constructed of the best materials, put together in the most substantial way, and with the best workmanship available. They should be located most conveniently as to distance for the greatest number of pupils. They should be away from noise and polluted air. The site chosen should be elevated and well drained. The playgrounds should be on the sunny sides, and they should be covered with natural gravel.

The aim of education is to develop the child physically, mentally and morally, to make a worthy member of society and a patriotic citizen. The child's mental education has been well taken care of, and it is time that a vigorous crusade be made to do justice to the physical child. Owing to progress in science, we have come to appreciate more generally the truth of the saying: "Mens sana in corpore sano" (a sound mind in a sound body). It is time for the physician to interest himself in the great problem of a healthy education. The physician, who interests himself in school matters, is better qualified than many others to judge wisely on matters pertaining to school and those conditions which undermine physical development. With his knowledge of the human body, and the amount of work which each organ is able to perform, he is able to call attention to the needed periods of rest between studies; he can make good suggestions as to the improvement of hygienic conditions of school-rooms, buildings, etc., thereby removing indirectly many causes of disease, and by practising these preventive

measures he can make himself invaluable to the community. Let the doctors of this body unite in the endeavor to improve the environment of the child at school, thereby assisting in rearing a stronger generation of men and women, who are better able to perform conscientiously the many duties of an upright, noble life.

A CASE OF CERVICAL SPINA BIFIDA—SYRINGOMYELOMENINGOCELE WITH HYDROMYELUS AND HYDROCEPHALUS.[1]

BY D. J. DAVIS, M.D.,
OF CHICAGO.

The reasons for reporting this case are chiefly two: (1) The uncommon occurrence of spina bifida in the cervical region, and (2) the very unusual and rare form of the condition met with in this instance. A brief report of the clinical history is as follows:

Female child, aged eleven weeks. Entered St. Anthony's Hospital April 10, 1904. It was the illegitimate first child of a mother aged nineteen years who was healthy in every way. The child was bright and active and gave absolutely no indication of any paralysis. There was a moderate degree of hydrocephalus with some bulging of the eyeballs and rather large fontanelles. Low down in the cervical region in the median line posteriorly was a tumor about the size and shape of a half lemon, slightly constricted at the base and projecting downward. This gave evidence of a distinct fluctuation, was elastic, rather tense, and could be compressed. The whole was covered by a skin distinctly thinner than normal and on the dependent side of the mass examination revealed a small dimple in which no opening could be detected on gross examination. No other deformity in the child was noted.

An operation was performed for the removal of the sac on the morning of April 14. An incision was made through the skin near the base of the tumor. None of the arches of the vertebræ were absent and an opening was seen about the size of a lead pencil between the seventh cervical and first thoracic vertebræ, through which passed a pedicle leading from the sac containing a fluid into the vertebral canal. In attempting to follow down the pedicle the sac was ruptured and a quantity of clear fluid escaped. The pedicle was followed down to within 1 cm. of the spinal cord and there ligated and cut. The sac and pedicle will be described later. The whole tumor was removed and the wound closed. The child's temperature soon began to rise after the operation and on the night of April 15 it died in convulsions, the temperature reaching 107° F. shortly before death. An autopsy was held the following morning and an anatomical diagnosis made as follows:

Acute fibrinous spinal and basilar leptomeningitis. Recent infected wound between scapulæ. Spina bifida of the cervical region. Internal hydrocephalus. Suppurative inflammation of the ventricles of the brain. Bronchopneumonia of the right lung. Acute parenchymatous degeneration of the heart, liver and kidneys. Hemorrhage into the spleen. Cysts of the ovaries. Uric acid infarcts in both kidneys.

Bacteriological examination was made of fluid obtained from the ventricles of the brain, the subdural space of the spinal cord, the peritoneal and pleural cavities and of the heart's blood and some bloody fluid about the operation wound. From all these sources the *Staphylococcus pyogenes albus* was obtained in large numbers and practically in pure culture. Smears made directly from the fluids except the heart's blood showed gram-staining cocci. They were especially numerous in the fluid from the lateral ventricles and from the subdural spaces of the cord.

The internal viscera generally showed nothing of importance beyond the marked acute degeneration due to the severe infection, and it is to the changes in the central nervous system that attention will be chiefly directed.

The head was considerably larger than normal, the fontanelles being very prominent and the cranial bones slightly separated. On opening the cranial cavity the brain was found to be very soft and the pia was hyperemic throughout. A few flakes of fibrin were seen at the base and along the course of the middle cerebral artery on both sides. The lateral ventricles, the third ventricle, the foramina of Monro and the aqueduct of Sylvius were all very much dilated and contained a purulent fluid. The thickness of the cortex of the brain in the region of the motor area measured from 1.5 to 2 cm. The ependyma lining the lateral ventricles was thicker and more resistent than normal.

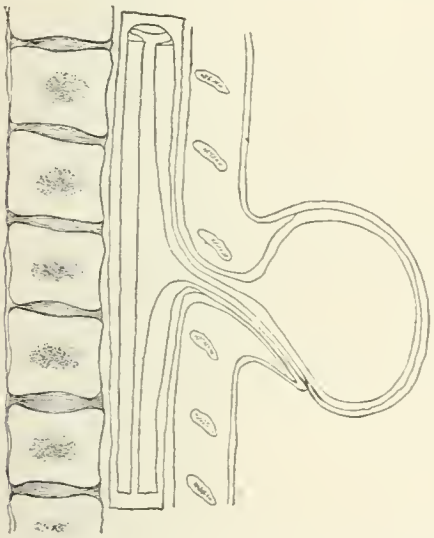
A recently sutured wound 4 cm. in length was present at about the level of the first thoracic vertebra. On cutting down upon the spinal cord some clotted blood was found outside the meninges. The dura was much distended by a purulent fluid and its inner surface was pink in color. The pia was very hyperemic and in places small flakes of fibrin adhered to it, especially in the portion near the seat of the operation. The vertebral canal was perfectly formed throughout except for the slight deformity above noted.

Spinal Cord.—The upper cervical, the greater part of the thoracic and the lumbar portions of the cord showed no changes on gross examination. At the level of the eighth cervical nerve there was a pedicle about 5 mm. in diameter projecting from the posterior surface of the cord. The base of this pedicle was broad and was formed largely by two ridges running up and down the cord corresponding to the posterior columns. This prominence of the posterior columns extended about 2 cm. above and below the pedicle. The length of the pedicle was nearly a centimeter, it having been sectioned at this point during the operation as already described. This short stump attached to the spinal cord on cross

1 From the Pathological Laboratory of Rush Medical College.

section was seen to be made up of three parts arranged concentrically. On the outside was the firm dura directly continuous with that of the spinal cord. Inside this was the delicate pia and in the center was a cord which showed on close examination a small opening in its center which apparently led into the central canal of the spinal cord. The sac removed at the operation showed on examination a smooth and rather tough lining directly beneath the integument. This ran down into the pedicle and though on account of the operation it could not be directly traced to the dura there can be no doubt that it is a continuation of this membrane. On the lower side of the sac beginning beneath the skin at a point just opposite the dimple is a small cord about a millimeter in diameter which runs along the margin of the sac and down into the pedicle, this being a continuation of the central part of the stump attached to the spinal cord. On microscopical examination this cord is seen to be a tube

Fig. 1.

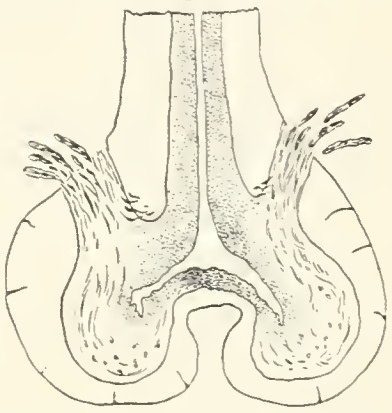


having a lining at least part of the way identical in structure with the skin and even showing sebaceous glands.

Figure 1 represents diagrammatically the relation of the various structures in the malformation, showing particularly the tube leading from the surface to the central canal and also the meningocele in relation with the subdural space.

Sections were made of the spinal cord directly through the pedicle and about 1 cm. above it; also through the upper cervical and through the lumbar and thoracic portions of the cord. The section of the cord through the pedicle (Fig. 2) shows a very much dilated canal triangular in shape, branches going out in the direction of the vertebral horns, and the other branch extending posteriorly, obliterating the posterior septum of the cord and passing into the tube of the pedicle. The fila of the nerves are not interfered with, and the posterior columns of the cord are simply pushed laterally. The ependyma of the central canal is well formed and may be seen extending for a distance into the pedicle. Around the central canal is a broad zone which is shown by special staining to be made up largely of neuroglia tissue. The section (Fig. 3) made about 1 cm. above the pedicle shows a central canal of much the same form. The canal here has also three horns, the posterior on passing up between the posterior columns pushing these outward and

Fig. 2.

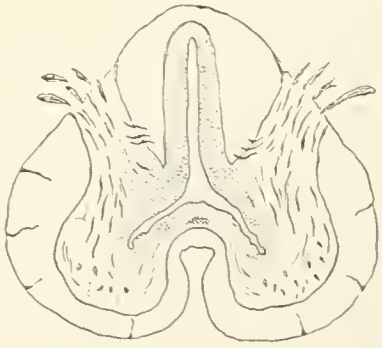


thus producing the ridge already referred to and the peculiar form as shown in the figure.

Sections through the lumbar, thoracic and upper cervical cord show a dilated central canal, it being especially marked in the cervical region. Sections at the various levels stained by the Pal-Weigert method show absolutely no degeneration of any of the fibers in the various columns.

To summarize, then, we have a condition of the central nervous system which shows a dilatation of the ventricles of the brain and their various communicating passages, a dilatation of the central canal of the spinal cord, and at the

Fig. 3.



level of the eighth cervical nerve a narrow tube leading from the central canal through a pedicle and opening on the lower side of the sac at the site of the dimple. The sac has a smooth lining which is apparently the dura and being in communication with the subdural space of the spinal canal may be considered a dilatation of the meningeal space. This is evidently then a meningocele, and because of the dilatation of the central

canal and the extension from the cord of a pedicle, the whole may be spoken of as a syringomyelomeningocele in combination with hydromyelia and internal hydrocephalus. There is therefore a general dilatation of all the cavities of the central nervous system with deformity of the spinal cord.

The above lesions indicate an imperfect development of the nervous system and from an embryological standpoint there is little difficulty in understanding what has occurred. During the developmental stages in the formation of the neural tube the edges of the medullary folds have for some reason failed to unite at a particular point and thus a communication has remained between the central canal and the surface. This very simple relationship as exemplified in this case in direct contrast to many cases of spina bifida which are often so difficult to interpret clearly is worthy of mention. It may be pointed out that it is in the upper dorsal region very near the location of the lesion in this case that the mural tube closes. From here the closing of the tube advances in either direction and consequently malformations are more common either higher up or lower down in the lumbosacral region.

The possibility of a rupture of the cord having occurred during fetal life, thus establishing a communication between the central canal and the outside, may with propriety be considered in this case. The delicate ventricles and central canal signifying probably an increase of pressure in these cavities, would tend to support such a consideration. This assumption would be in accord with the ideas of Förster and other German writers who look upon many cases of spina bifida as due to a dropsy of the central canal. Although it is difficult in many cases of spina bifida to understand how such a process might operate to produce the result, in such a case as the one here presented, the idea is quite plausible.

Von Recklinghausen thinks that most cases of spina bifida are due to an unequal growth of the canal and the cord and as a consequence a bending of the cord occurs in order to accommodate itself to the spinal canal; but this can apply only in certain cases and apparently need not be considered here.

The literature is particularly scant upon cervical spina bifida. As to its rarity one may obtain some idea from the report of the committee appointed by the London Clinical Society in 1885 to investigate spina bifida and its treatment. In a series of 125 specimens examined from various museums, not one case of pure cervical spina bifida occurred. In a series of 243 cases collected from the literature or specially reported to them the location of the tumor was stated in 226 and in this number there were 0 cases of cervical and 2 of cervicodorsal spina bifida; 4 of these 11 cases had hydrocephalus. Clutton [1] reports a case almost identical with the one here reported except that there was some dilatation of the pedicle of the cord about the meningeal sac; also there was no hydrocephalus and no hydromyelus except a slight dilatation of the central canal near the pedicle. Von Langenbeck has also reported a case of cervical spina bifida with a fissure leading into the central canal and with hydrocephalus. A number of cases of cervical spina bifida have been reported by surgeons, but as a rule a careful study of their structure had not been made and they were reported as simple meningoceles.

MEDICAL PROGRESS.

MEDICINE.

Dangers of Illuminating Gas.—The perils of the domestic use of modern fuel and illuminating gas, now so generally used, are pointed out by Dr. H. LEFFMANN (*Journal A. M. A.*, June 3). The coal gas formerly employed was comparatively non-toxic, and its characteristic odor was a danger warning, but the modern water gas that has so largely replaced it in common use, with its larger content of carbon monoxide and its comparative lack of odor, is far more dangerous. Accidents from this cause are far more frequent than formerly, and carbolic acid and illuminating gas have replaced, at least in Philadelphia, he says, for suicides and accidental poisonings, the arsenic and laudanum of the Civil War period. A sleeper can easily absorb a fatal amount of modern water gas without being aroused, and Leffmann shows by a simple calculation how a very small percentage of carbon monoxide—less than one-half a grain, for example, to 100 c.c. of blood—can render useless its hemoglobin. Gas stoves for cooking are used generally only in warm weather when natural ventilation is good, and the danger from them is therefore lessened, but their burners are seldom furnished with a collar to regulate the air supply, and the combustion is therefore liable to be irregular and deleterious gases are given out. Gas "stoves" or heaters connected with the gas pipes by rubber tubing are objectionable on account of the liability of leakage, which is very great unless the very best tubing material is used. The stopcock on the heater is especially objectionable, as it is the one most convenient to use, and when used the leakage through the tube can go on unchecked. The precautions recommended by Leffmann are: Prevention of sale of inferior tubing; having no stopcocks on heaters unless they are connected to house mains by metal pipes with tight joints and such construction as will prevent the rubber tube, even when of the best quality, remaining in free connection with the house main when the gas is not lighted. He would also have heaters constructed so as to give a larger radiator effect with a given gas consumption, and would have them placed only where the products of combustion can escape freely into the chimney. All burners on the Bunsen principle should be provided with collars to regulate the air supply, and purchasers should be instructed in their use. The commonly used illuminating mantles may also be objectionable by interfering with combustion, especially when worn or displaced, and the flexible tube of the ordinary drop-light be also a source of danger like that of the heater.

Chronic Acetanilid Poisoning.—D. D. STEWART (*Journal A. M. A.*, June 3) reports two cases of acetanilid addiction, one of them at considerable length, and

refers to others in the literature. The symptoms in the severer cases of chronic poisoning by the coal-tar products are, he remarks, very similar as regards mental and physical debility. There is cardiac weakness, more or less pronounced cyanosis, and blood changes characteristic of the action of a hemolytic agent. But for the leucocytosis, the blood conditions would almost suggest pernicious anemia with their dimunition of the erythrocytes and changes in their size and shape, the presence of erythroblasts, often in larger numbers than pernicious anemia, of polychromatophilic cells, and of cells undergoing protoplasmic granular degeneration. There is usually a notable increase of blood plaques and a leucocytosis is common, the increase, it is reported, being usually in the polymorphonuclear elements. In Stewart's cases, however, which were uncomplicated, there were 37 and 35 per cent., respectively, of lymphocytes. He thinks that possibly in other cases there might have been some complicating disease influencing the leucocytosis and the proportion of polymorphonuclears. In Cabot's case, complicated with nasal carcinoma, while the blood had the characteristic chocolate hue, and the hemoglobin was therefore not estimable, there was a leucocythemia. Erythroblasts were lacking, methemoglobin was demonstrable in both blood and urine, and the patient's general condition was good in spite of the evident cyanosis. Such a case might superficially suggest, he says, the condition that has lately attracted considerable attention, chronic cyanosis with polycythemia and enlargement of the spleen. The difficulty sometimes attending the diagnosis in these cases has been noted by others, and stress has been laid on the characteritic anemia, etc.

Tumor of the Third Ventricle of the Brain.—R. T. Williamson (*Med. Chronicle*, May, 1905) adds one case to the eleven in the literature on this subject. While the presence of an intracranial growth was diagnosed during life, its exact location was only determined post mortem. The case recorded by the author presented simply the general symptoms of intracranial growth for a long period; the mental condition was not affected until the terminal coma commenced to develop; and indications of affection of the third, sixth and fifth cranial nerves did not occur until the last few weeks of life. In the eleven cases of tumor of the third ventricle which the author has collected from the literature, the nature of the tumor was as follows: sarcoma, 2; carcinoma, 1; papillary carcinoma, 1; papillomatous tumor, 2; colloid cystic tumor, 1; epidermoid cyst, 1; fibroid tumor, caused by mycotic infection, 1; chondrocystosarcoma, 1; actinomycosis, 1.

Hepatogenous Levulosuria.—The action of the various organs upon some sugars has been tested by E. Sehrt (*Zeitsch. f. klin. Med.*, Vol. 56, Nos. 5 and 6). Desiccated spleen, liver, etc., had very little influence upon glucose, but with pancreatic powder active glycolysis took place. This was still more marked if muscle power was also added, no matter if a third organ was present or not. It follows that the decomposition of glucose within the body probably requires the action of both pancreas and muscle. The extracts of these two tissues are, however, unable to split up levulose, and the experiments of the author prove that this property is possessed to a slight degree only by the liver and the salivary glands. This will explain why, with deranged function of the liver, levulose will appear in the urine if a certain amount of this sugar be given by mouth.

Nature of Diabetes Insipidus.—Careful study of several patients suffering from insipid diabetes, by Erich Meyer (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 1 and 2), tend to throw a good deal of light upon the nature of this obscure disease. It was found quite constantly that if patients secreting 10,000 or more c.c. of urine are put on a certain diet the amount of urine will often fall as low as 3,000 c.c. without giving rise to disagreeable symptoms. This diet consists solely of carbohydrates and fats, some fruit, preferably applesauce, being permitted to quench the thirst. If meat or salty food is given during this treatment the amount of urine voided will again increase rapidly. If the total daily quantity of urine be examined before and during treatment it will be found that while the amount varies very much the total quantity of nitrogen and chlorides excreted will remain about the same for the twenty-four hours. It may be stated, therefore, that diabetes insipidus is an affection of the kidneys, which does not enable these organs to void the urine in its normal concentration. To avoid retention of excrementitious matter more water will be necessary, and hence the thirst will be excessive. It is absolutely wrong to deny these patients water, since serious disturbances will follow. The diagnosis of diabetes is occasionally difficult since hysterical polydipsia, non-bacterial pyelitis and other conditions may give rise to the same symptom complex. Much information can here be obtained by changing the diet and by giving salt: if a nitrogenous diet and a dose of 20 grams of salt are followed by a marked increase in the amount of urine with little change in the concentration the case is most likely one of insipid diabetes, while if there is no pronounced variation in the amount, but a higher percentage of salt and nitrogenous matter, another diagnosis must be made. The ability of the kidneys to excrete concentrated urine, if the amount of excrementitious matter in the blood is large, is called the concentrating power; the reverse, the diluting power. In parenchymatous nephritis both the concentrating and the diluting powers are very much diminished; that is, the food and the amount of water ingested change the amount and the concentration of the urine but slightly. In interstitial nephritis the concentrating power is much diminished, but the diluting power almost normal. In hysterical conditions both concentrating and diluting powers are normal, while in insipid diabetes the concentrating power is lost altogether, but the diluting power is normal. A slight increase in concentration may, however, be brought about here by means of therapeutic doses of theocin. Phosphate of soda will not increase the amount of urine either in health or in diabetes insipidus.

Cyanosis of Enteric Origin.—A very peculiar symptom complex was described several years ago under the name "autotoxic, enterogenous cyanosis." The patients exhibit a marked cyanosis of the skin and the visible mucous membranes, the end phalanges of the fingers are enlarged and a severe diarrhea is generally present. Spectroscopic examination of the blood showed a broad band in the red portion of the spectrum, which was generally attributed to methemoglobin. Subsequent reports of similar cases have not been very numerous, but A. A. Hijmans and V. D. Bergh (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 1 and 2) have been so fortunate to observe a child with atresia ani and urethro-rectal fistula, which presented all the typical symptoms. By careful examination of the blood it could be determined that the cyanosis was not due to methemoglobin, but to sulf-hemoglobin, a compound of hemoglobin and sulphureted hydrogen, absorbed from the intestines.

The amount of gas in the blood was too slight to be detected by chemical means, but the spectrum of the artificial product corresponded in every way with that of the blood. Besides, a large amount of sulphureted hydrogen gas could be obtained from the artificial cultures of the bacteria isolated from the intestines. The gas occurs normally in the intestines of all individuals, but absorption to any degree does not take place unless very large amounts are formed, or unless, like in this case, the intestines are distended, owing to obstruction below.

Prolonged Fever of Unknown Cause.—Every physician will occasionally encounter prolonged febrile conditions which do not permit of a diagnosis, despite the most careful examination of the patient. Some of these cases turn out to be chronic, septic endocarditis; in others, the temperature is due to latent tuberculosis or to pyelitis. The development of malignant tumors, particularly of the stomach and the mediastinum, may give rise to temperature and the tertiary stage of syphilis, especially if gummata are present in the liver, may be the cause of the fever. The case of V. KRAUSE (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 1 and 2) deserves to be put on record since a diagnosis was impossible even after the autopsy. The chief symptoms were marked chill, profuse perspiration, slight cough and expectoration, developing directly after a severe exertion. The subsequent fever was of intermittent type, but repeated examination of the organs and of the blood and the various excreta failed to reveal the cause. The cachexia gradually increased and after several months the patient died. All the organs were examined microscopically and bacteriologically, but no characteristic lesions or bacterial growth could be obtained. In conclusion, the author draws attention to the value of blood-cultures; in another obscure case on the type of recurrent fever, a pure culture of proteus could be obtained.

Blood-Cultures in Gonorrhea.—In cases of gonorrhea with complications, A. PROCHASKA (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 1 and 2) recommends that blood-cultures be made since he has found them quite often positive; 10 c.c. or more of blood are removed from a vein at the bend of the elbow and added to 200 c.c. of a mixture of ascitic fluid and broth in the proportion of 1 to 3. In several days an iridescent membrane will form on the surface of the culture medium, made up of characteristic gonococci. It is a mistake to believe that cases with positive findings will always be fatal, since as many as four out of six cases observed by the author recovered. The complications which led to an inundation of the blood with germs were: Suppurating inguinal nodes with erythema nodosum, polyarthritis with endocarditis, and lastly, purulent meningitis.

Curschmann's Spirals in Bronchial Asthma.—Although Leyden was the first to demonstrate in 1872 the presence of special spiral bodies in the secretions of bronchial asthmatics, it was not until Curschmann, in 1883, defined their diagnostic value that the real nature of these new formations became more or less clearly established. According to him, a bronchial secretion that contains spirals is a clear indication of an impending asthmatic attack. PREDTECHENSKY (*Prak. Vrach*, March 19, 1905) reports the case of a patient who had been a sufferer from asthma for the last fifteen years. She expectorated daily two tablespoonfuls of a viscid mucus that contained Curschmann's spirals, a number of Charcot-Leyden's crystals and a great quantity of eosinophile bodies. By a method of his own the author succeeded in staining and isolating the spiral bodies from the patient's secretion and arrives at the conclusion that they are simply accumulations of mucus or mucopus extended to a great length and turned upon a longitudinal axis; the various forms of these spirals simply depend on the length of the filaments and the degree of revolutions around the axis. The principal constituents of these bodies are the eosinophile-leucocytes, the mucus forming mainly the connective element. The spirals, however, are not specific for bronchial asthma, but the special bronchial secretion out of which these spirals are formed during an attack of asthma, as it consists of mucus and an enormous number of eosinophiles which later give rise to the Charcot-Leyden crystals. The attack of asthma is evidently a secretory neurosis due to disturbance of the function of the sympathetic nerve. With this there is also a motor neurosis—a tonic spasm of the bronchial muscular fibers, as evidenced by the peculiar dyspnea of an expiratory type.

Cirrhosis of the Liver.—In speaking on the etiology of this subject, R. SAUNDBY (*Practitioner*, June, 1905) states that many cirrhotic livers are met with from many sources of origin. The chief and nearly invariable cause of the condition is the excessive use of alcoholic drinks. It has been suggested by some writers that the true cause is not the alcohol, but some other substances present in association with it. Lancereaux, for example, has pretended that it is due to the potassium sulphate resulting from the plastering of wine, but the disease follows the abuse of such different kinds of alcoholic drinks, *e.g.*, gin, rum, whisky, liqueurs, wine and beer, which, having alcohol in common, vary otherwise so much in the material from which they are manufactured and the processes they undergo that the ordinarily received opinion seems to be the most reasonable. This view by no means pretends to explain the pathological process, or shuts out the possible agency of microbes, or their toxins, especially the *Bacillus coli communis*, as suggested by Adami and others. The effect of the alcohol may be to depress the vitality of the liver cells and thereby favor the invasion of that organ by the intestinal bacteria. Adami has shown that dead specimens of the *Bacillus coli communis* may be found in any section of normal liver, but in the cirrhosed liver of man and cattle these organisms are not only present in numbers, but full of vitality. It is also possible that the abuse of pepper and spice by Europeans in tropical climates aids the effects of alcohol on the liver, for Tinozzi has shown that the addition of pepper or capsicum to the food of dogs and rabbits causes, after a certain time, a distinct increase of the hepatic connective tissue. It was formerly usual to attribute the "liver," which the old-fashioned Anglo-African brought home with him, to the abuse of curries and pilans, and it is possible that we are not quite right in looking so exclusively to alcohol and malaria as the causes of tropical liver, although the above-named dishes are not so generally used in India as they were a hundred or even fifty years ago. The author considers that the symptoms of alcoholic poisoning show themselves many years earlier in the nervous system than in the functions of the liver. He does not consider that alcohol is late in attacking the liver, but the point is that cirrhosis of the liver does not cause any marked clinical symptoms in its earlier stages, and passes for years unperceived. In fact, men in apparently good health have been known to die suddenly from some other

cause, or have been seized with a first but fatal hematemesis, and on post mortem the liver has been found to be in a state of extreme contracted cirrhosis.

SURGERY.

The Choice of Methods for the Radical Cure of Prostatic Enlargements.—The complete removal of the prostate has been attended with remarkable success as well in patients of advanced age and enfeebled by long suffering, as in men between the ages of fifty and sixty years, whose general health has not been much impaired by their local diseases, so that to-day it is merely a question of which method offers the best results and the lowest mortality. John C. Pardoe (*Med. Mag.*, June, 1905) reviews the different methods of treatment and considers the advantages and disadvantages of each. The author is inclined to the belief that the suprapubic route gives the best practical results. The salient points about this operation are: (1) The speed with which it can be accomplished; (2) the incision into the bladder can be made of a size to suit the delivery of any sized prostate; (3) the fact that the compressor urethra is not damaged if the operation is properly performed; (4) the ease with which coexisting calculi can be removed; (5) the completeness of relief given to the obstruction, and, so far as we know at present, the permanence of this relief; (6) the complete absence of sequelæ, such as stricture and incontinence. The objections to this operation are: (1) Difficulty in the control of hemorrhage; (2) the enucleation is done entirely by the sense of touch; (3) the destruction of the common ejaculatory ducts; (4) drainage, often of a very septic cavity, has to take place against gravity and through two wounds; (5) it is necessary for patient to remain in bed at least a fortnight to three weeks. The operation by the perineal routes are of two types, the deliberate dissections and the rapid enucleations. The advantages claimed for perineal operations are that everything is done under the guidance of the eye, all hemorrhage is stopped as it arises, the bladder cavity is not opened and dependent drainage is secured. The disadvantages are: (1) It is long and tedious; (2) complete enucleation is not always performed; (3) recto-urethral and recto-vesical fistulæ are too common; (4) dense strictures are liable to result; (5) permanent incontinence is a frequent sequelæ: (6) on account of the narrow space it is often extremely difficult to remove large prostates. In the treatment of hard, contracted prostates, which cannot be enucleated entire, the author considers that in median perineal prostatectomy we have an excellent method of effecting a cure.

The Separation of the Urine of Each Kidney.—The desire for more accurate knowledge of the condition and secreting power of each kidney has in recent years stimulated the efforts of surgeons in the perfection of the technic of genito-urinary surgery, particularly cystoscopy, urinary segregation, and ureteral catheterization. H. W. T. Walker (*Practitioner*, June, 1905) presents the subject very thoroughly. In renal disease there are two problems confronting the surgeon, (1) which kidney is diseased? and having decided this, (2) what is the functional power of the healthy or less diseased kidney? The first question is readily decided by the physical signs in most cases, yet the source of hematuria or pyuria requires the separation of the urine secreted by each kidney. The question as to whether the second kidney is sufficiently healthy to undertake the entire renal function, or, indeed, does a second kidney exist, must be decided. In the settlement of this question there are two methods at our disposal: Separation of the bladder into two halves by a septum and draining each half, and catheterization of the ureters. The methods at present in use for collecting the urine of each kidney separately are two. In one the bladder is artifically divided into two compartments and the urine drained separately from each kidney. The instruments which represent the most perfect mechanism are those of Luys and Cathelin. The second method is by means of a catheter cystoscope, by which the urine from each kidney is collected directly from the ureters without the intervention of the bladder. The instruments of Nitze, Casper and Albarran are the ones giving the best satisfaction. The following types of cases are given by the author as suitable for the use of these instruments: (1) Cases in which an operation is proposed on one diseased kidney, and information is desired in regard to the function of the second kidney; (2) cases in which hematuria or pyuria of known renal origin is present, but it is uncertain which is the diseased side.

The Causes of Appendicitis.—In considering the causes of appendicitis, F. C. Bottomley (*Practitioner*, June, 1905) treats of the etiology under three heads: (1) The variety of micro-organisms found in the disease; (2) why this part of the bowel is more liable to inflammation than other parts, and (3) the individual predisposing conditions. Under the first class the organism most frequently found to be present is the *Bacillus coli communis*. The streptococcus is a frequent cause. The following organisms have also, though less often, been found: The *Staphylococcus pyogenes aureus* and *Staphylococcus citreus*, pneumococcus, the *Bacillus pyocyaneus*, *proteus* and various anerobic and putrefactive bacilli, as have also the bacilli of influenza, diphtheria, glanders and tetanus. Actinomycosis is a rare cause. Tuberculous and typhoid ulcers may occur in the appendix. The conditions which make the appendix more liable to attack by micro-organisms than the rest of the bowel are: (1) Its great amount of lymphoid tissue; (2) the bacterial activity is at its maximum in the cecum; (3) its previous diseased condition; (4) gross lesions which are contributing causes, as concretions, ulcers, narrowing of the lumen at one point, true foreign bodies; (5) the appendix may be kinked, bent at an angle or twisted around its long axis, it may have a very short mesentery. Under the individual predisposing conditions may be mentioned: (1) Constipation; (2) the use of purgatives; (3) indigestion; (4) bad teeth, and (5) the uric acid diathesis.

Surgical Importance of the Cervical Rib.—While the supernumerary ribs of the lumbar vertebræ have only an academic interest, those of the cervical region, as Carl Beck (*Journal A. M. A.*, June 17) points out, have a real practical importance. The observations of disturbances due to a cervical rib are multiplying every year. The anomaly may vary from a slight growth just extending beyond the transverse process to a complete rib with a cartilage uniting with that of the first rib. It is bilateral in two-thirds of the cases, but a complete rib on both sides is a rarity. When not complete, or nearly so, it may give rise to no special symptoms, and before the use of the Roentgen ray it was comparatively seldom diagnosed during life, and most of the reported cases were, therefore, accidentally discovered at autopsy. Even when it caused trouble, the symptoms were often credited to tumor or other causes than cervical rib. It is probably, therefore, a more common anomaly than might

appear from the small number of cases reported. Though of congenital origin, it does not cause trouble until about the twentieth year, a fact that is hard to explain. The principal symptoms of the anomaly are a hump-like prominence in the lateral cervical region, a superficial pulsation of the subclavian artery and the appearance of pressure symptoms in the brachial plexus. The trouble is a mechanical one, and the treatment, when required, must be surgical. It is just as foolish, Beck remarks, to remove a cervical rib which causes no disturbance as it is to leave one that does cause disturbance until lasting tissue changes have been brought about. At times the technic is very simple, but in the majority of cases difficulties are met, and it should be done only by an experienced surgeon. The difficulty is enhanced by the necessity of removing the periosteum, as otherwise recurrence may be expected. Beck finds that a triangular flap incision, running directly downward along the trapezius and then conducted toward the sternum about one inch above the clavicle, fully exposes the field of operation. If the trapezius cannot be sufficiently retracted with a broad retractor, a transverse incision must be made into the muscle, for, next to a strict asepsis, the success of the operation depends on extensive exposure of its field. The brachial plexus, which usually runs across the rib, can be pushed aside: the subclavian artery is best pulled forward. The scaleni are done by using a Cooper shears and, advancing layer by layer, lifting the several muscle fibers with the flat of the scissors and using the instrument like a grooved director. By means of a ring-shaped periosteotome the rib is then freed of any small muscular appendages. The division is easy with Beck's beak-shaped rib shears, but some may prefer the Gigli saw. Any remains are nipped off with rongeur forceps.

On Echinococcus Cyst in the Thyroid.—This is one of the rarest tumors associated with this gland, and only 22 cases are thus far known. A case of particular interest on account of its retrosternal position in the anterior mediastinum and the difficulties attending its removal, is reported by O. EHRHARDT (*Berl. klin. Woch.*, April 17, 1905). The patient was a man aged twenty-one years, who reported that about three years previously he began to notice a growth which gradually appeared and grew up from behind the sternum. This was followed by severe dyspnea, difficulty in swallowing the cardiac palpitation. An operation was necessary for the relief of symptoms and was done under Schleich anesthesia. The tumor was quite large and involved a number of neck muscles. It was found necessary to exacuate it and then the true nature of the growth was revealed. Extirpation was completed with difficulty, the trachea being involved and some of the cartilagenous rings partially destroyed. As soon as the removal of the tumor was accomplished, relief from symptoms was immediate. The wound was sutured and the man made a good recovery. Some two years later, no recurrence had taken place.

Gastric Disturbances in Appendicitis.—It is to the credit of E. PEYR (*Münch. med. Woch.*, April 25, 1905) to have shown that many of the gastric disturbances seen with appendicitis are caused by embolic processes resulting from thrombi in the vessels of the mesentery or the omentum. If an emulsion of oil or paraffin be injected into the mesenteric veins of animals, it is almost always possible to bring about the formation of characteristic ulcers in the mucous membrane of the stomach with hemorrhage. In man the source of the thrombi is either the omentum or the appendix, with its mesenteriolum and the thrombi are caused by the infection itself or by the handling of the abdominal contents during the operation. Ulceration may also occur in the duodenum or other parts of the intestinal tract, though this is certainly very rare. Embolic processes are somewhat more common in the lungs and the portal system.

PHYSIOLOGY.

The Toxicity of the Urinary Alkalodis.—It has been shown by H. GUILLEMARD and P. VRAUCEANO (*Comptes Rendus*, May 8, 1905), that silicotungstic acid may serve to separate from the urine a number of bodies which show most of the reactions for alkaloids. The authors sought to discover the proportion which the alkaloidal toxicity bears to the total toxicity of the urine. They find that it is 18 to 25 per cent. Kreatinine has no influence on the alkaloidal toxicity, which does not vary in the same sense as the total toxicity, and is not proportional to the quantity of alkaloids, but depends on the nature of these substances.

The Production of Alcohol and Acetone by the Muscles.—An explanation of a possible source of some of the acetone that may accumulate in the blood in pathological conditions, is afforded by the research of F. MAIGNAN (*Comptes Rendus*, April 17, 1905), who finds that a muscle removed from an animal and placed under conditions favorable for survival, produces both acetone and alcohol. The former constantly increases, but the latter increases only for the first few days, and then diminishes. The tissues are able to destroy alcohol after it is formed, but have no influence over the molecule of acetone. The alcohol is probably transformed into acetic acid by a direct or an indirect oxidation. The acetic acid then undergoes the fate of all other organic acids in the body, namely, a transformation by odixation, into carbon dioxide and water. The transformation of glucose into alcohol may be considered a mode by which the body is able to destroy glucose.

A New Method of Testing for Formalin in Milk.—The altogether too common use of formalin by milk-dealers gives importance to the communication of E. NICOLAS (*Comptes Rendus*, April 17, 1905) on a new method of discovering this toxic substance in milk. This test consists in the precipitation of the casein by means of acetic acid (up to 10 per cent.), filtration, and then adding to the filtrate some crystals of amidol, or amidophenol. In the presence of minute quantities of formalin (1-50,000) there occurs a canary-yellow coloration.

The Biligenic Function of the Spleen.—It has for a long time been thought that some intimate relationship exists between the spleen and the liver. An investigation of this problem was made by MM. CHARRIN and MOUSSU (*Comptes Rendus*, April 17, 1905). In animals subjected to cholecystotomy with the formation of a biliary fistula, it was found that a subsequent splenectomy caused a change in the quality of the bile. This gradually suffered a loss in color, and a diminution in its specific elements. The conclusion is drawn that the spleen, by virtue of its hemolytic function, provided the coloring matter, salts, and other substances which enter into composition of the bile by the liver.

Glycemia due to Ablation of the Mammary Glands.—The removal of the mammary glands in an animal about to give birth to young causes, according to M. PORCHER (*Comptes Rendus*, May 8, 1905), the appearance of a large quantity of sugar in the blood with a resulting glycosuria. This is easily explained by the fact that the sugar which ordinarily would go to the mammary glands, to be converted into lactose, is thrown back upon the blood, and finally secreted by the urine.

The Reduction of Oxyhemoglobin.—A new method that may be of value in clinical diagnosis, and which

consists in a measurement of the time taken to reduce the oxyhemoglobin in a specimen of blood, has been discovered by R. Lépine and Boulied (*Comptes Rendus*, April 10, 1905). Jabonley reported in 1904 a case of surgical shock following a prolonged anesthesia, in which the time for the reduction of hemoglobin removed from the patient was delayed. With this as a hint the authors sought to determine whether this delay occurs in any other conditions. Samples of blood in which the amount of hemoglobin was carefully determined were then subjected to the reducing action of certain agents, and the time that it took before the absorption-bands for oxyhemoglobin to disappear was noted. The reduction-time of the oxyhemoglobin of the blood of a normal dog is generally between eighteen and twenty minutes. Dilution of the blood has no effect on the reduction-time. In anemia the reduction-time is greatly increased. The prolonged inhalation of ether or chloroform has the same effect. Microbic infection, even with a very virulent staphylococcus, with a strong febrile reaction, has no effect on the reduction-time. In normal venous blood this time is usually three minutes less than that of arterial blood.

Action of Intestinal Juice upon the Secretory Activity of the Small Intestine.—By injecting intestinal juice into the blood of an animal it was found by A. Frouin (*Comptes Rendus*, April 17, 1905), that the amount of intestinal juice secreted was markedly increased. It was also found that the substance in the intestinal juice which stimulates this increased production is not a ferment, since it is not precipitated by diluted alcohol and is not destroyed by heat. Hence it cannot be secretin.

Philocatalase and Anticatalase in Animal Tissues.—The discovery of anti-ferments and anti-anti-ferments in the blood has been established on sound experimental foundations. T. Baggelli and Mlle. L. Stern (*Comptes Rendus*, May 1, 1905) have given the name anticatalase to a ferment capable of destroying catalase in the presence of oxygen. Anticatalase is found in the spleen, liver, and lung. Moreover, in several tissues as well as in the blood there is a ferment which has the power of destroying anticatalase, thus protecting catalase. To this ferment the authors give the name philocatalase, and they find it present in the organs in which the anticatalase is also present, and in the same proportion as the latter.

Variations of Osmotic Pressure in the Contracting Muscle.—Attempts have been made to explain the muscular contraction on the basis of surface tension. S. Leduc (*Comptes Rendus*, May 1, 1905) finds that the contracting muscle causes an elevation in the osmotic pressure in the muscle. This increases with the increased strength and duration of the contractions, and with the increase in work performed by the muscle. These changes cannot fail to have a profound, if not a unique, influence on fatigue.

The Favorable Effect of X-rays in Non-Suppurative Tuberculous Adenopathies.—A report of three cases, showing the favorable effects of the X-rays in swollen glands of the neck was made by J. Bergonié (*Comptes Rendus*, March 27, 1905). The cases presented a chain of swollen indurated glands fixed to the deeper tissues, which had resisted all other forms of treatment. A number of exposures to the X-rays caused a disintegration of and diminution in size of the glands, which, however, did not entirely disappear. That the improvement was really due to the X-rays was shown by the fact that some of the glands which were shielded from the rays remained unchanged. Further experiments are promised by the author.

Treatment of Cerebrospinal Meningitis with Pilocarpine.—A large number of cases of cerebrospinal meningitis have been treated successfully with pilocarpine by V. Voryzek (*Wien. klin. therap. Woch.*, May 21, 1905), after all other remedies had been tried and the condition seemed hopeless. The drug was always given by mouth in daily doses of 5 to 7 centigrams for adults and 2 to 5 centigrams for children. It was always borne well, since bad after-effects are only common after hypodermic injections. The action of the drug is probably the same as in pneumonia; a leucocytosis is set up, which enables the body to successfully combat the invading germs.

OBSTETRICS AND GYNECOLOGY.

The Metritis of Virgins.—It has been a subject for dispute among gynecologists whether the virgin uterus is ever subject to a true metritis. P. Dalché (*Arch. de Therap.*, April 15, 1905) takes an affirmative view and states the following as causes of metritis in the unmarried. First of all is gonorrhea, which is frequently contracted innocently by young girls. Other causes are poor hygiene during the early menstrual life, a narrow introitus vaginæ, causing retention of menstrual fluid and congenital maldevelopment of the uterus. The symptoms of vaginal metritis are dismenorrhea, menorrhagia, pains in the hypogastrium, and leucorrhea. The treatment is the following: The application of a number of leeches to the hypogastrium, in order to reduce the pelvic congestion, the wearing night and day of hot fomentations over the hypogastrium, the administration of mild laxatives (it may be mentioned that a number of cases of false metritis are the result of pelvic congestion due to constipation, and the use of sedative sitz-baths containing leaves of nightshade, belladonna, hyoscyamus, each 30 grains; also add to the water two crushed poppy-heads. In addition to this the patient should get vaginal injections. For this purpose, use injections of the following:

R Eucalyptus leaves 10
Aquæ 1000

Filter and add one soupspoonful of bicarbonate of soda.

The Effects of Sexual Incontinence During Gestation. There are a number of grounds for the belief that sexual intercourse should be avoided by the pregnant woman. Ch. Féré (*Arch. de Neurologie*, April, 1905) believes that, besides the greater liability to abortion which may result from this practice, injurious consequences to the unborn infant may result. He cites the case of a young child exhibiting many of the traits of degeneration, the offspring of healthy parents, with a history of excessive intercourse during the pregnancy of the mother. He believes that this practice harmed the fetus during its early intra-uterine life. The author believes that during early pregnancy, owing to the release from the fear of additional offspring, the amount of sexual intercourse indulged in may be excessive. This was the case in the instance cited. The possible injurious effects on the future of the offspring should decide in favor of the rule that during gestation coitus should be interdicted entirely.

Technic of Ventrosuspension.—The object of the operation of ventrosuspension is to secure the uterus to the anterior abdominal parietes forward in an exaggerated normal position, so that subsequently a ligament is formed or pulled out to maintain the uterus in its normal position. Such a ligament must not involve a wide area of uterine parenchyma, and should be of such a character as to undergo hypertrophy and hyper-

plasia during the growth of a pregnant uterus. In view of the occasional failure of the Keely operation, H. D. Beyea (*Am. Jour. Obstet.*, April, 1905) suggests a modification which has proved successful in over four hundred cases. The silk suspension sutures are passed from without through rectus muscle, one-quarter of an inch from the margin, through peritoneum and uterine tissue and out through peritoneum and muscle on the opposite side. Two such sutures are introduced, one-quarter of an inch apart, and tied with just sufficient tension to bring the uterus firmly in contact with the peritoneum without cutting through muscle tissue. The ligamentary support formed through this operation is always single and is believed to contain muscle fibres from both uterus and rectus, an advantage in its hypertrophy during gestation and in its contractile power during the puerperium.

Results of Ventral Suspension of the Uterus.—G. R. Holden (*Am. Jour. Obstet.*, April, 1905) has made a study of the postoperation history of 445 cases in which the operation of ventral suspension had been performed at the Johns Hopkins Hospital, which led to the following conclusions: (1) Successful symptomatic results after suspension of the uterus may be expected in about 60 per cent. of those cases in which the retroposition is the sole or most prominent abnormal condition. (2) Fifty per cent. to 60 per cent. of all cases of dysmenorrhea in which retroposition is the most prominent abnormal condition, are relieved of the dysmenorrhea by suspension of the uterus. (3) The suspension ligament is usually a band or one or two cords, 3 to 5 cm. long. (4) The majority of patients who have had the operation performed have no adverse symptoms referable to the suspension during pregnancy or labor. The most frequent adverse symptom is abdominal pain during pregnancy. (5) Recurrence does not necessarily follow after labor, but may occur. If labor does not intervene the number of recurrences is not more than five per cent.

Varicose Veins of the Broad Ligament.—The presence of varicose veins in the broad ligament constitutes a condition worthy of recognition as a clinical and pathological entity. Most gynecologists pass them over with the assumption that they are secondary and will disappear with the correction of the causative lesion. They may be overlooked because they do not manifest themselves when the patient is prone or in the Trendelenburg position. The veins of the broad ligament lie in two groups under the ovary and low down in the ligament near the internal os. The anatomical peculiarities that predispose the spermatic veins to varicocele in the male are alike present in case of the ovarian veins. The monthly engorgement of the uterus and the vascular distention demanded by the pregnant uterus are etiologic factors not found in the male. After a study of those cases in which there is no complicating conditions to which the symptoms might be attributed, S. M. Miller and A. B. Kanavel (*Am. Jour. Obstet.*, April, 1905) consider the subjective symptoms of varicose veins in the broad ligament to be a disturbance of menstruation, which is apt to be prolonged, profuse and frequent and a sense of fulness, weight and tension in the pelvis, increased on standing and relieved on assuming a reclining position. In secondary cases the symptoms are inseparable from those of the causative conditions. The physical examination should be made with the patient standing and the broad ligament palpated through the rectum and the vagina. The varicose veins are felt as a baggy mass, a subinvoluted uterus is usually present, hemorrhoids, varicosities of the vulva and a bluish tint to the mucous membrane of the vagina may be noted. The disease is clinically curable, the treatment consisting in ligation and excision or section of the veins, with such treatment of the ovaries, tubes and uterus as may be indicated.

PRESCRIPTION HINTS.

Treatment of Erysipelas.—W. F. Waugh (*Med. Standard*, June, 1905) recommends in the treatment of erysipelas the use of pilocarpine in sthenic cases, and iron in asthenic cases. During a period of twenty-five years he has had good results with this line of treatment, and no deaths. No local treatment is recommended. In sthenic cases the pilocarpine is given every hour until sweating occurs. When this takes place the edges of the involved area begin to recede. This remedy is then suspended for a day, and if the eruption continues the treatment is resumed until it is evident that the remedy has perfect control of the disease. In asthenic cases the tincture of the chloride of iron, thirty drops every four hours, and nourishment crowded, when improvement sets in at once.

Lotion for the Treatment of Eczema.—

R Potassii chloratis.....1 gr. 50
Vini opii.....2 gr. 50
Aq. dist.....1,000 gr.

M. Dissolve. Saturate compresses with this solution and apply them upon the parts affected by the eczema. If the inflammation is very acute, begin the treatment by a warm bath of the affected parts and the use of poultices made of powdered carbonate of lime.—*Journal de Medecine de Paris.*

Antihemorrhoidal Ointment (West).—

R Extract of henbane.....
Tannin..... aa 5 gr.
Petrolatum.....90 gr.

—*Journal de Medecine de Paris.*

Treatment of Corns (Brocq).—Soften the corn at night by covering it with a piece of flannel coated with soap and some spirits of wine. Afterward scrape it with a curette or a knife. Apply on eight successive days a layer of the following collodion:

R Alcoholic extract of cannabis indica...0. gr. 5
Salicylic acid.. .....
Alcohol (90%)..... aa 1 gr.
Ether .....2 gr. 50
Flexible collodion.....5 gr.

M. F. s. a.

On the eighth day, after bathing the foot for a long time in hot water, scrape away with a curette or knife the mass of collodion, and along with it the greater part or all of the corn. If necessary, the treatment may be repeated.

A common and often efficient remedy is to place upon the corn a round piece of lemon during one or several succeeding nights.

Cantharideal collodion, or salicylic ointment is also used. Different caustics should be used with extreme caution. Surround the very painful corns with a special ring of wool or a corn plaster. When the corn is situated between the toes, keep the latter separated with a pad of fine cloth, and dust the corn with a powder of tannin, alum or oxide of zinc. Certain authors recommend the following method: (1) Moisten the corn with a concentrated solution of salicylic acid in alcohol; (2) cover with powdered salicylic acid and make a sealed covering with a small piece of cotton wadding; (3) renew the dressing in four or five days, and if there is any inflammation, stop the treatment. About the eighth day remove the corn by soaking.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 12, 1905.

THE HYPERTROPHIC REACTION.

It requires scarcely more than a superficial survey of recent investigations in the domain of pathology, to note that the laws underlying morbid processes are no different from those that govern biological phenomena in general. The discovery made by Virchow over fifty years ago, that the normal body cell is the anatomical unit of all pathological formations, may now be supplemented by the revelation of equal importance, namely, that the mechanisms of both physiological and pathological processes are identical.

One of the most comprehensive of all biological principles is that of adaptation. Upon this conception has been erected the grand superstructure of organic evolution. The experimental investigation of the ways in which various organisms react to changes in its environment has already yielded substantial results.

While de Vries and his followers will continue to till this fertile field of research among the lower forms of animal life, the pathologist and clinician, as well as the physiologist, will no less be able to note the applications of this basic principle in the highest of all organisms.

It is hardly necessary to allude to all of the numerous examples of adaptation in the normal body. Without dwelling on the various forms of compensatory hypertrophy, which have been recognized for a long time, one may recall one of the recent brilliant researches on the digestive ferments. Thus it has been shown that the pancreas is capable of adapting itself to a change in diet by changing the character of its secretion. To be more explicit, if dogs be fed on milk-sugar, their pancreatic juice will soon be found to contain lactase, although this ferment is under other circumstances not found in this secretion.

About a year ago, in an article entitled "The Biological Interpretation of Cancer," in the Medical News, Dr. A. Spingarn placed malignant neoplasms in the same category with the various forms of physiological hypertrophy. To quote this article, "the explanation of these forms of hypertrophy may be sought in the fact that when the cells of a tissue are incapable, as the result of some irritation, be it chemical, parasitic, or mechanical, of doing the work allotted to them, then these cells will proliferate in order to produce other cells, the activity of which will make up for the embarrassed function." According to this view, the secret of all forms of hyperplasia, both physiological and pathological, is to be found in some form of interference with normal activity.

Among the various forms of tissue overgrowth, there is none of such universal occurrence, appearing in almost every individual who has passed middle life, none which is nearly as much responsible for chronic disease, and none which has so stoutly resisted all therapeutic efforts, as the connective-tissue hyperplasias. If the cause of these could be clearly revealed, then the mystery of Bright's disease, emphysema, myocarditis, etc., will have been solved.

In the light of what has already been suggested as to the adaptive reactions of the organism, one may attribute the connective-tissue hyperplasias to some form of antecedent irritation. This view is certainly in harmony with the results of clinical observation. Thus, among the etiological factors of Bright's disease, are to be mentioned alcohol, lead poisoning and gout, which are also responsible for other diseases due to connective-tissue proliferation. That these diseases are fundamentally of toxic origin has suggested important possibilities from the viewpoint of preventive medicine. Indeed, Metchnikoff has gone so far as to attribute the sclerotic changes of senility to toxins absorbed from the alimentary canal.

At the recent meeting of the Association of

American Physicians at Washington were read two important papers bearing directly upon this subject. One of these was by Dr. A. O. J. Kelly, of Philadelphia, and dealt with the pathology of cirrhosis of the liver. This author pointed out that while it is the custom to think of the overgrowth of connective-tissue as the cause of the fibrosis, the study of the parenchyma has been neglected. In the course of the destructive process, there is an overgrowth of liver-cells. The beginning of cirrhosis is attributed to some cell poison which produces necrosis of liver-cells at a time when the liver is capable of making up for its loss by hyperplastic reaction. The essential feature in cirrhosis of the liver, instead of being atrophy, as is commonly thought, is really, in the majority of cases, a hypertrophy, even in the advanced stages of the disease.

Dr. Richard M. Pearce, of Albany, N. Y., was the author of the other paper, which dealt with the experimental aspect of this subject. It was Kretz who first advanced the theory that cirrhosis of the liver is the expression of the conservative process of repair by which nature seeks to mend the damage inflicted upon the liver parenchyma. Pearce experimented on dogs, with the view of producing necrotic changes in the liver. For this purpose he injected hemolytic immune sera of high hemagglutinative power. These produced thrombi composed of fused red blood-corpuscles. The resisting obstruction of the circulation produced necrotic foci in the liver. The process of repair following these lesions was minutely studied. There first occurs a mitosis of the liver cells lying at a slight distance from the necrotic areas, occurring thirty-eight hours after injection. At the end of forty-eight hours there is a proliferation of endothelial and connective-tissue cells, which increases so rapidly that in five days the necrotic tissue is almost entirely replaced by young granulation tissues. The only difference between this artificial cirrhosis and that seen in man, is that the cirrhotic process does not occur at the periphery of the lobule as in man, but near its center. This slight topographical difference, however, does not affect the important biological significance of these experiments.

These researches afford another illustration of the latent reparative energies of the body, of which the closing in and final obliteration of a tuberculous cavity in the lung is a familiar example. While in most instances this new connective-tissue formation is a purely conservative process, in some instances it may overstep the strict limits of repair, and may become, in itself, a pathological menace.

The hypertrophic reaction must, therefore, be regarded as identical with the capacity of regeneration normally possessed by all living tissues. Two types of regeneration may be distinguished, namely, the normal and the abnormal. In the former the process of repair proceeds at a rate and to a limit just sufficient to restore the part or function that has been lost or damaged. In the latter, the persistence of some irritant causes an extravagant prolongation of the regenerative forces. As an example of the normal type, the formation of ordinary scar-tissue may be cited, while the formation of exuberant granulations and of keloid serves as an example of the abnormal type of regeneration. It is to the latter that the various pathological hyperplasias belong.

This entire subject has little to offer from the viewpoint of active therapeutics, but from that of preventive medicine it is pregnant with possibilities. The rôle of various irritants and other destructive agents in the production of the various hypertrophies and hyperplasias has been clearly indicated. A truth which the physician is best fitted to circulate abroad is, that the "simple life" has a physical as well as a spiritual connotation.

THE PHYSIOLOGY AND THERAPEUTICS OF THE MEDULLARY SUBSTANCE OF THE SUPRARENALS.

Anatomically two distinct portions of the suprarenals have been recognized—the cortex and medulla. The latter has been termed the paraganglionic portion, since in certain particulars it resembles in structure the sympathetic ganglia, from which, indeed, it has been derived. The utter disparity between the cortex and the medulla both histologically and genetically suggests that these portions have distinct functions in the animal economy. The unique place which the adrenals have won in modern therapeutics has been achieved in spite of a disregard of these two diverse portions of the organ, since the suprarenal extracts that are being so largely used are obtained from the entire organ.

It has remained for certain Italian investigators to probe into the physiology of the medullary portion and to discover its peculiar therapeutic virtues. In February, 1903, Professor G. Vassale and Dr. A. Zanfrognini reported to the Medico-Chirurgical Society of Modena the effects of ablation of the medullary substance of the adrenals. This is followed in cats by acute symptoms and death, from which the authors concluded that the medulla, which is the more important part of the chromaffin tissue, has the function of secreting, like the rest of this tissue, a substance which is necessary to the economy. It preserves the cardiovascular tone, acting directly upon the smooth-muscle fibers, exciting their contraction and maintaining their tone. It also bears some relation to the bodily metabolism, acting like a ferment in regulating the biochemical exchanges and preventing auto-intoxication.

In June of the same year, Vassale reported that the ingestion of an extract of the medullary portion of the adrenals has an action which is five times as energetic as that of the adrenalin of commerce. He found that it had a particularly favorable effect upon the muscle of the gastro-intestinal canal. It caused a surprising improvement both in the local and general condition of individuals suffering from atonic gastrectasia and peristaltic atony, associated with neurasthenic symptoms; these were cases of several years' duration. This observer also found that the active principle of the adrenals is not affected in vitro by the gastric juice, and when administered by the mouth it passes into the blood vessels of the stomach unaltered, preserving its characteristic action. He therefore considered that this method of administration is rational and is indicated in the various forms of gastric and intestinal atony, in the different neuroses, and in spinal and mental diseases in which are found as marked symptoms, cardiovascular and atonic gastro-intestinal troubles with marked general asthenia. This investigator proposed to replace the names adrenalin and suprarenin with the term "paragangline," which designates more precisely the secretion of the medullary portion of the suprarenals.

Vassale was not the only one to observe the peculiar medicinal virtues of this portion of the adrenals. U. Baccarini and A. Plessi reported their results in the treatment of fourteen cases of gastric atony by means of daily doses of from forty to sixty drops of the medullary extract, in divided doses four to eight times a day. The effect of the drug does not last long, hence the necessity of frequent dosage. The results were rapid and brilliant and persisted after the cessation of the treatment. The gastric symptoms were relieved through an augmented mobility of the stomach. As accessory effects, the authors observed an increase in the pulse-rate and of the cardiovascular pressure, an augmentation in the amount of urine, of ureic nitrogen and of phosphoric acid excreted, which indicates an acceleration of the oxidative processes of the organism.

Another clinician, G. Guiciardi, reports similar results (*Rivista Sperim. di Freniatria*, Fasc. 1, 1903). He employed the paragangline (Vassale) in various neuropathic conditions with or without gastro-intestinal symptoms, and in cases of scrofulous glandular enlargements. The action upon the stomach and intestine was always prompt and efficacious. In general asthenia there is always an increase in the amount of energy put forth and in the sense of well-being. The metabolism is notably increased in cases of senile epilepsy with arteriosclerosis and in old and torpid glandular enlargements. No intolerance to the drug was observed.

The above unanimous verdict as to the usefulness of paragangline in conditions which are not very uncommon, arouses the hope that clinicians in this country will give this drug a trial, and that manufacturers will soon place this at our disposal.

TO FILTER CROTON WATER.

Dr. Darlington, the Commissioner of Health, recently made a report to the Mayor in which he strongly expresses his conviction that filtration is necessary in order to protect the people of New York against the invasion of disease germs. The reasons set forth include the arguments which have long been familiar to the student of public hygiene, although some of them have, in this instance, been drawn out to a somewhat unusual tenuity: the impurities of the water are increasing, and are likely to increase still more in the future; there is an increasing difficulty in the way of properly protecting the water-sheds against pollution; the authority and laws governing the means by which the sanitary condition of the supply can be protected are imperfect; the death rates from typhoid fever and diarrheal diseases are unnecessarily high; filtration is an economical process when its cost is compared with the value

of the lives saved. It is usually possible in such arguments to point to a high typhoid fever death rate as a reason for filtration, but in New York this is fortunately impossible: New York has one of the lowest death rates from typhoid of any of the large cities of America, and a considerable part of it is believed to be due to the consumption of polluted shellfish.

The cost of a plant for filtering the Croton water has been estimated at $17,000,000; the cost of operating it, including repairs and depreciation, at a sum which, if capitalized, would be $900,000. It is said that the work would be completed in two years.

The report of Dr. Darlington, dated July 25, 1905, is not the first move in the project for a filtration plant for the Croton. This project was started by the Commission of an Additional Water Supply, who recommended that "work be immediately begun for the filtration of the Croton supply." It is understood that the Aqueduct Commission would have undertaken to carry out this recommendation, but were blocked by the fact that the Corporation Counsel expressed the opinion that the Commission did not have the necessary legal power to do so. The New York Water Board apparently has no more power in this respect than the Aqueduct Commission, and although it undoubtedly would be in favor of the plan, it cannot be expected to carry it out at present unless the Board of Aldermen move on the Health Commissioners' report or a recommendation is made by the Mayor.

Meanwhile there need be no alarm. Opinions cannot differ as to the ultimate need of filtration plants to purify the Croton, but analyses and statistics show that the water is not unwholesome now. If the Central Park reservoirs were kept properly cleaned and the works and drainage areas maintained in a proper manner there would be no fault to find with the supply at present. The filtration of the Croton is a large project. In view of the uphill work usually necessary before purification works would be built in any city, the agitation for a filtration plant in New York has been begun none too soon.

Typhoid Fever at Bay Ridge.—Bitter complaint is made by the residents of Bay Ridge, following the spread of typhoid fever to that section, the neighborhood of Fort Hamilton and South Brooklyn, because they have recently been deprived of water from the artesian wells at Utrecht and Gravesend. This perfectly pure water supply, they say, has been diverted to Coney Island and they have been furnished instead with water from the Ridgewood Reservoir.

ECHOES AND NEWS.

NEW YORK.

Epidemic Cerebrospinal Meningitis.—The situation in New York is weekly improving, only 24 new cases for the week ending August 5, 1905, having been reported. The number of cases of typhoid fever is slowly rising at this time, 122 cases having been reported during the same week.

Phthisiophobia in Middletown.—Vigorous opposition has developed to the establishing of a sanitarium for tuberculosis patients on the top of Shawangunk Mountain, at Otisville, by the Board of Health of New York City. The opposition is led by the Erie Railroad and its army of commuters living near New York City. E. H. Barto, suburban passenger agent of the Erie, was in Middletown last week and has been working hard to get the Orange County Board of Supervisors to rescind its action granting permission for the sanitarium. Both the county and town authorities have been given permission and New York City has commenced laying out the grounds.

Washington Heights Hospital Appeal.—This hospital, a new charitable institution at One Hundred and Seventy-fourth Street and Broadway, was opened to the public on August 1. The hospital is in immediate need of an ambulance service to cover the large area in which the population of Washington Heights is contained, and the authorities take the liberty to solicit voluntary subscriptions to provide an ambulance outfit as quickly as possible. Washington Heights is already one of the most populous sections of the city, and in five years will have over half a million people above One Hundred and Forty-fifth Street. The only hospital in the vicinity at present is at One Hundred and Thirty-first Street and Amsterdam Avenue, two miles from the center of the new heights district.

New York State Tuberculosis Hospital.—The retirement of Dr. Pryor from the superintendency of the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis at Ray Brook, continues to excite interest and comment throughout the State. Those who are familiar with the facts, writes *Charities*, believe that the troubles at Ray Brook have been aggravated by the failures to provide a business head for that institution in the form of a competent steward. This failure imposed upon the medical superintendent of the institution work which should never have been placed upon him, and the result was, under those circumstances, a foregone conclusion. It is well known, says *Charities*, that for some reasons of his own that have not yet been fully developed, the fiscal supervisor of State Charities has been seeking to get rid of the stewards at some of the institutions, with the result of throwing a large amount of extra work on the superintendents. This experiment was tried at the House of Refuge for Women at Hudson, with bad results, and, finally, after the superintendent had been obliged to take a lengthy vacation to recover from the extra strain upon her, a steward was again employed. Through the influence of the fiscal supervisor, the board of managers of the Ray Brook hospital were obliged to do without a steward and to satisfy themselves as best they could with the services of a "bookkeeper, storekeeper and purchasing clerk."

The Loeb Memorial Home.—Plans have been completed for the Solomon and Betty Loeb Con-

valescent Home, to be established by the children of those in whose memory it is named at East View, Westchester County. The site is the former Harris farm, an estate of more than seventy acres, situated on an elevation, with a commanding view. In addition to the land, the sum of $750,000 has been given for the institution, of which $500,000 has been set aside as a permanent income-producing fund, while the remainder is to be used at the discretion of the trustees for the erection and equipment of the home. As stated in the *Evening Post* last April, the purpose of the foundation is to provide an opportunity for the enjoyment of wholesome surroundings in the country to recent sufferers from acute diseases, so that they may sufficiently recover their strength and health before again entering their vocations. Besides actual convalescents, it is intended to receive persons who are in poor physical condition from anemia or similar troubles; but no attempt is to be made to cure either acute or chronic diseases. A mansion now on the site of the home is to be removed entirely, as it did not prove to be adaptable for the purposes of the institution, and the new administration building is to take its place, situated between beautiful groves of old pines and other fine trees on the crest of the hill. Distributed about this, at distances of from 200 to 300 feet, will be three cottages, one for men, one for women, and one for children. These cottages will be as homelike as possible, and every effort will be made to exclude the impression of a hospital. The main or administration building is to have large foyers and extensive porches. On the main floor will be a music room, large and small dining rooms, and pantries, while in the basement will be a smoking and billiard room, servants' dining rooms, the kitchen, and provision rooms. The second story will contain the apartments of the superintendent and the matron, an emergency hospital, storerooms, toilet rooms, etc., and a number of rooms for the reception of about ten convalescents before they are assigned to the detached cottages. In the cottage for children will be two separated dormitories for twelve persons each, with large dining rooms, playrooms, a reading room, and a sun parlor on the ground floor. Each of the two other cottages is to contain thirteen bedrooms for one or not more than two occupants each, with one living room, joint toilet, and bathrooms, and an apartment for the nurse. Large porches will be a feature of these structures. All the buildings on the grounds will be two and a half stories in height, and will have brick walls covered with plaster work, except that the outside of the children's cottage will be half in timber work. The architecture of the cottages is to be of old English style. A central plant will provide for the hot-water heating and supply all the buildings.

Yellow Fever in the Past in New York.—While residents of Manhattan Island during the last half-century, writes the *Evening Post*, have enjoyed almost complete immunity from yellow fever, only sixty-eight deaths having occurred since 1852, according to statistics on file in the Board of Health, the period previous thereto saw several epidemics which in many cases changed the entire complexion of sections of the city by the inhabitants leaving the infected districts and going to others. As early as 1706, in the days of Lord Cornbury, New York was visited by the fever, which was brought from St. Thomas. Every one who could fled either to New Jersey or Long Island, Lord Cornbury with his retinue, taking up his residence in Jamaica. It appeared slightly up to 1747, but in 1791, it again visited the city, and was confined to a limited region about Burling Slip. Early in the summer of 1795, in the midst of political commotions, a British frigate entered New York Harbor with several cases of yellow fever on board. The disease spread rapidly through the city, and continued to rage till the coming on of the cold weather. A large portion of the inhabitants fled from the city and nearly all forms of business experienced a complete stagnation. The whole number of deaths by the fever amounted to about seven hundred and fifty, or about 1½ per cent. of the whole population. In 1798 the epidemic returned again, and although it did not appear till near the beginning of August, it greatly exceeded in fatality that which had preceded it. More than two thousand persons died of it, or one-tenth of the population. An investigation into the cause of this epidemic made by "a large and respectable committee of the citizens, the physicians, and of the corporation," presented only the ordinary causes of disease in large cities. Among these they enumerated "deep, damp cellars, public slips containing filth and stagnant water, burials in the city, narrow and filthy streets, tippling houses (more than a thousand were licensed that year), and want of a supply of pure and wholesome water." It appeared again yearly in modified degree until 1805, when it raged with considerable violence, producing great panic and flight from the city and seriously deranging business. Mrs. Lamb, in her "History of New York," describes the epidemic of 1798 in the following words: "Many were seized with it before they had heard of its presence. Nearly one-half of the cases reported in the month of August proved fatal. The horror of the situation was greatly increased by the alarm of the country people, who ceased bringing their country produce to market. The relief committee appealed through the newspapers for supplies of poultry and small meats, an appeal which met with a bounteous response. Business was suspended, and schools and churches closed. Washington Square, purchased for a burial place by the corporation in 1796, became a potter's field indeed, and not only strangers and common people, but many persons of note were buried within its limits." The visitation of the fever in 1803 stopped the work for a time on the building of the City Hall, and Mayor Livingston is said to have remained at his post, regarding himself bound, as by a sacred contract, to face the terrible enemy and alleviate suffering. Livingston was stricken with the disease, but recovered. Twelve years later New York was again the seat of this dreadful scourge. Hemstreet's "Story of Manhattan," describing it thus: "In the year 1815, after the battle of New Orleans, everything was going along smoothly when all at once the yellow fever broke out on the West Side, far down town. It raged with even more violence than had the smallpox. Citizens fled, and the stricken district was fenced off, so that no one might enter it. It was like a place of the dead, silent and deserted. Many people went far out of town to Greenwich Village, and many business houses opened offices in this little settlement, with the result that Greenwich Village started on a new life, and it was not long before it grew to be an important part of New York, instead of a suburb. For many who had transferred their business, also went to live there, not returning to the city even

after the fever had passed away." In July, 1819, the fever reappeared. A few fatal cases occurred in the neighborhood of Old Slip, but did not extend farther. But in 1822 it broke out suddenly in Rector Street, and soon extended through the vicinity and up to Broadway. The epidemical character of the disease was marked, and exceedingly malignant, and the contagion unusually active and violent. By the middle of August the epidemical atmosphere overspread all that part of the city that lies below the park, and the entire population of the infected district fled before it. The Custom House, banks, and other offices were closed and abandoned, or removed to temporary quarters in Greenwich Village. High board fences shut off each infected street or district below City Hall. Ferry boats landed their passengers far uptown. The markets were removed to Chatham Square and Hudson Street, near St. John's Park. Multitudes fled the city, and many dwellings were hastily constructed in the upper wards, especially at Greenwich Village. The disease lingered until autumn. The fever did not reappear until the year 1852, from which time up to last year the following deaths have occurred: 1852, 1; 1853, 5; 1854, 6; 1855, 2; 1856, 13; 1858, 5; 1895, 4; 1860, 2; 1864, 2; 1867, 3; 1868, 1; 1869, 1; 1870, 3; 1871, 2; 1873, 3; 1876, 1; 1877, 1; 1879, 2; 1880, 1; 1884, 3; 1885, 1; 1886, 1; 1888, 3, including the death from yellow fever of the Astronomer Proctor, who died in the Clarendon Hotel; 1892, 1; 1898, 1 (Colonel Waring was the only victim this year).

PHILADELPHIA.

Starvation as a Means of Escaping the Penalty of Murder.—In order to defeat the purpose of James Salerno, who set out to starve himself to escape the penalty which will fall to his lot for the murder of his stepdaughter, Sheriff Riddell, of Williamsport, subjected the convict to violent exercise, which induced him to take the food he had refused for five days.

Wound of the Heart Sutured.—While attempting to do voluntary police duty Alonzo J. Currington received a wound of the heart which almost proved fatal. The knife used by the patient's adversary punctured the left ventricle. After receiving the stab Currington walked 50 yards, caught the wagon which he protected and asked the driver to take him to the hospital to have the wound attended to. Dr. John Gibbon, of 332 South Fifteenth Street, Philadelphia, reached Bryn Mawr Hospital soon after the occurrence of the accident and placed five sutures in the heart muscle. Lying in the same ward is a boy who punctured the pericardium and tore the heart muscle slightly by falling upon a pitchfork. His wound was also sutured; both patients are getting well.

The Results as Revealed by the Investigation of the Schuylkill River.—Two years ago when the Reading sewage filter plants were examined by the State the bed was constructed with sand which is now substituted by grit, which permits the sewage to pass through rapidly but retains little or none of the solid substances. Each filter bed is cleaned once every twenty-four hours and the contents are dumped upon a large pile about 100 feet from the river so that with each heavy rain much of the filter materials are washed into the river. Along the banks of the river between Reading and Phœnixville the stream was found polluted by washings of stables and outhouses. French Creek, which is near Phœnixville, receives the discharges of slaughter houses and the water of the old canal into which the discharges of the gas works are thrown. Many of the street sewers in Norristown empty directly into the river and in Conshohocken all the surface water reaches the river. Farther down the stream the closets of the railway station and of the small villages drain into the river. The same pollution occurs at Manayunk. The canal of the last-named place is a source of great pollution on account of the class of people who inhabit its banks; they pay little respect to the laws of sanitation.

CHICAGO.

City Department of Health Adopts System of Food Inspection.—The city health department is sending inspectors to all market districts of the city, and kerosene is poured upon the condemned food to prevent its sale. The inspectors attacked the Ghetto, and 8,000 pounds of fish, 70 crates of bananas, 185 crates of pears, 620 crates of peaches, and 15 tainted calves were condemned in one day. Milk dealers will also be visited by the new "flying squadrons."

Music Treatment Aid to Insane at Dunning.—"Better than barrels of medicine and much more effective than straps or straight-jackets." In these words Dr. B. H. Podstata, general superintendent of the asylum for the insane at Dunning, summed up his opinion recently, after observing for two hours the effect of music upon an audience composed of insane men and women patients. The concert given for the inmates of the Dunning asylum was more pretentious than any previous entertainment there. Four hundred of the 1,800 patients under Dr. Podstata's charge were assembled in the big hall of the institution and there sat more attentive than many an audience of persons supposed to be possessed of their full mental faculties. Many of the listeners were patients from violent wards, who were constantly under the watchful eyes of their keepers, but none of them gave any cause for anxiety. From the moment of the first number on the program until the conclusion, the audience sat in rapt attention and vociferously applauded each selection. Patients who in their wards are continuously restless, muttering and gesticulating, sat quiet and subdued. One patient, known to be violent, made no more serious demonstration than to rise and move his lips at each outburst of applause. A few of the dull faces did not respond to the charm of the music, but these were rare, and the features of most of the listeners plainly displayed interest and admiration.

Demand for Clean Bill of Health.—In connection with the recent outbreak of yellow fever in New Orleans and elsewhere, Dr. James A. Egan, Secretary of the Illinois State Board of Health, has issued the following notice to railroads: To the General Managers of Railways Entering the State of Illinois: The Illinois State Board of Health hereby orders that until further notice no passengers from New Orleans or other points in which yellow fever has appeared or may appear in the future, shall be permitted to leave trains at any point in the State of Illinois south of the line of the Baltimore and Ohio Southwestern Railway, running from East St. Louis on the west to Vincennes, Ind., on the east. Certificates of health from officials in the infected districts of the south will not be ac-

cepted for the transportation of passengers into that section of the State of Illinois lying south of the line above described until ten days after said passengers have left the infected districts. No passengers from Louisiana, Florida, Alabama, or any other States in which yellow fever has occurred or may occur in the future shall be carried to any point in Illinois south of the line of the Baltimore and Ohio Southwestern Railway, unless provided with certificates of health, signed by national, State or municipal health officers. Inspectors of the Illinois State Board of Health will board all trains passing through the district south of the line of the Baltimore and Ohio Southwestern Railway. Passengers coming from points north of the above-described line will be required to show that they have not been in infected municipalities for ten days prior.

GENERAL.

Congress of Radiology and Ionization.—The first International Congress of Radiology and Ionization will take place at Liège, Belgium, September 12 to 14, inclusive. The Congress will be made up of two sections, one devoted to physical problems, the other to biological ones.

Car Sanitation in Minnesota.—At the last meeting of the Minnesota Board of Health the executive officer was instructed to draw up certain rules and regulations regarding car sanitation, these to be considered in conference with various railway officials and reported upon at the next regular meeting of the board. In carrying out its inquiry, four points are emphasized by the Minnesota board: (1) A sufficient amount of fresh air properly distributed; (2) cleanliness of the car and its contents, including closets; (3) the proper heating of the car; (4) overcrowding. All of these points relate to railway coaches, street cars and sleeping cars. Opinions have been asked by the board as to whether they are given all of the consideration they deserve by the companies operating in Minnesota, and the question is asked whether the board shall undertake to secure better sanitary conditions by formulating certain regulations. Circular letters have been sent out to a number of citizens in Minnesota and the character of the replies will influence the board in its decision.

Thomas Jefferson on Yellow Fever.—A correspondent to the New York *Sun* writes, in part, as follows: A strange coincidence is noted by those familiar with yellow fever epidemics of New Orleans, which have occurred at stated intervals, viz., 1853, 1867, 1878 and 1905, that invariably they have broken out in the same section of the "Old French Town" that caused the immortal Jefferson when President, in December, 1804, to write as follows to Gov. Claiborne: "The position of New Orleans certainly destines it to be the greatest city the world has ever seen. There is no spot on the globe to which the produce of so great an extent of fertile country must necessarily come. It is three times greater than that on the eastern side of the Alleghanies, which is to be divided among all the seaport towns of the Atlantic States. In the middle and northern parts of Europe, where the sun rarely shines, they may safely build cities in solid blocks without generating disease; but under the cloudless skies of America, where there is so constant an accumulation of heat, men cannot be piled on one another with impunity. Accordingly, we find this disease (yellow fever) confined to the solid built parts of our towns, and the parts on the waterside, where there is most matter for putrefaction, but rarely extending into the thinly built parts of the towns, and never into the country. In these latter places *it cannot be communicated. In order to catch it you must go into the local atmosphere where it prevails.* Is not this, then, a strong indication that we ought not to contend with the laws of nature, but should decide at once that all our cities shall be thin built?" After these introductory observations, Jefferson expressed the opinion that in building cities in the United States the people should take the checkerboard for their plan, leaving the white squares open and unbuilt forever and planted with trees. He observed to Claiborne: "As it is probable that New Orleans must soon be enlarged, I enclose you this same plan for consideration. I have great confidence that however the yellow fever may prevail in the old part of the town, it would not be communicated in that part which should be built on this plan, because this would be like the thin built parts of our towns, *where experience has taught us that a person may carry it after catching it in its local region, but can never communicate it out of that.* Having very sincerely at heart that the prosperity of New Orleans should be unchecked, and great faith, founded I think on experience, in the effect of this mode of building against a disorder which is such a scourge to our close built cities, I could not deny myself the communication of the plan, leaving it to you to bring into real existence if those more interested should think as favorably of it as I do. For beauty, pleasure and convenience it would certainly be eminent."

Canal Zone Death Rate Low.—There is a strong feeling in the War Department and the Marine Hospital Service, writes the New York *Sun*, that the public has an exaggerated idea of the unhealthful conditions on the Isthmus of Panama. The death rate, considering the tropical climate, is regarded as low, even under present conditions; the death rate among canal employees is remarkably low for any climate, and it is pointed out that the great work of sanitation inaugurated by the United States Government authorities is only in its early stages. "What is the record? During the entire year 1905 the death rate, in spite of reports to the contrary, has been kept to a remarkably low percentage. The authorities have the great problem of sanitation well in hand, and it is just as certain that they will make the Canal Zone healthy as it is that American pluck and energy will build the canal." A comparison between the conditions which obtained during the first year of canal work under French administration and present conditions shows that the United States officials are solving the question of sanitation. In 1881 the French reported an average force of 928 men on the Isthmus, with a death rate of 66.8 per thousand, while in the Ancon hospital alone the deaths from yellow fever reached the proportion of 23.7 per thousand. The death rate in the Canal Zone among both the 10,000 employees and the uncounted non-employees during the last three months was only 2.6 per thousand, counting the fatalities among both classes and omitting from the equation a number of non-employees. This would make an annual mortality of less than 10 per thousand. The death rate in Washington is 20 per thousand or more. There were but 26 deaths from fever in the Canal Zone during May, June and July, and of this number only 15 were employees, an annual rate of 6 per thousand only. The number of cases of fever, most of which recovered, decreased from 72 in June to 28 in July, due presumably to the scientific efforts of the sanitary officers in screening, cleaning, draining

and taking such other extraordinary precautions as were taken in Cuba in 1898 and 1899. The authorities here say it should be kept in mind that since De Lesseps' time science has solved the problem of checking yellow fever. The United States, therefore, has overcome what seemed to be to the French an unsurmountable obstacle. The marked decrease in the number of cases in what may be considered one of the worst months of the year is also due in part to the new water supply for the city of Panama, that was first turned into the mains on July 4. With half pressure on a six-inch main twelve streams of water were thrown higher than the Administration Building, and this pure water is now turned in on several mains through the center of the city. Faucets have been attached to the hydrants and the people are now provided with free water. The advantages of this improvement can only be appreciated, the War Department officers say, by those who are acquainted with conditions that formerly obtained, and can scarcely be overestimated. Another important change that is expected to add to the health of the Isthmus is now well under way and that is the establishment of comfortable quarters along the entire line of the canal. By the end of the present month every non-immune employee can be comfortably lodged outside of Panama and Colon, which appear to be the only two foci of the diminishing fever on the Isthmus. Plans are also under consideration looking to the establishment of a refrigerating system, so that meat, vegetables, eggs, butter, poultry and other food stuffs can be brought from cold storage in the United States, transported in cold storage by vessels to the Isthmus, and then distributed by refrigerating cars to the ice-boxes of the hotels and boarding houses along the line of the canal. With the installation of this service the personnel of the canal will be properly housed, will have pure water, will be well fed, and the question of proper sanitation will, it is believed, be solved. The most efficient scientists and engineers have told the War Department that they are thoroughly convinced that eventually the Isthmus will be a pleasant and agreeable place of abode. They say that the fever is not indigenous to the Isthmus. The nights are cool, and, with the exception of a period in the middle of the day, the heat is not oppressive.

The Alaska Trip of the American Medical Association.—The meeting of the American Medical Association, which has just been held in Portland, has had an element of success that was due wholly to the hospitality of the Portland physicians and their wives. The formal discussions of medical matters which appear in print are of but faint interest compared with the intimate personal exchange of opinions concerning practice, ethics and ways and means of men living under conditions as varying as those in New York and Duluth, or New Orleans and Seattle. Given an equal number of delegates to any European congress, one would find a bar to intimacy in language, religion and nationality. But at this meeting on the western coast the physicians who met in Portland were typically American, men who had merged the foreign birth and breeding of ancestry in the universal citizenship, and who dropped the language of science for the language of friendly intercourse, and without barriers of reserve showed themselves as they were, the genial, sympathetic family physician, the scientific student, the agitator for educational advancement, and the specialist of every branch. Never has there been such a protracted opportunity for the physicians of our land to compare notes. Under the guiding eye of the energetic committee of Portland, who saw to the gathering of the clans, the physicians found themselves congregated in parties and brought in special trains through the Yosemite, or the Yellowstone, or the Canadian Rockies, with facilities for returning in parties by another route when they had been able to determine their choice, based on the enthusiastic reports of those whom they met at the convention. The whole trend of the entertainment was for the better acquaintance of men who had met but yesterday, and for the reunion of old friends. To this end there were receptions at the homes of the physicians, and in the large buildings at the Fair Grounds. There was a day spent on the Columbia River, with salmon fisheries and great snow-capped peaks for diversion, and a beautiful salmon banquet served by the ladies in a grove of pines far up the river. There was a reception and a supper and much diversion at The Oaks, the new pleasure resort of Portland. In fact, no moment outside of business hours was left unfilled with entertainment. But the crowning event of the trip was the expedition to Alaska, which was planned with every detail of care for comfort and for extensive sight-seeing. The enthusiasm for this trip was so high that by the time the meeting was over another boat could have been filled had numbers signified their desire in time. As it was, the early applicants were fortunate, and almost one hundred and fifty, physicians, wives, sons and daughters, went to Seattle, where the local physicians had rushed home in time to lunch and dine them and show them their city before the party sailed in the steamship Jefferson.

Puget Sound, at the sunset, with its snow-capped Olympic Range, and the great white peak of Mt. Baker, is a sight long to be remembered, and clear weather at the start enabled the party to have this view as a climax to the first day's panorama. Nor did the weather fail at the critical moments, for when the party reached Lynn Canal and the great White Pass the skies were clear and the weather warm, and continued so through the rest of the trip. In fact, the balmy weather and the sunny, flowery aspect of Alaska was as much of a surprise to those who had accepted their impressions from school books as was the wonderful railroad over the White Pass to those who had so recently read of the rush to the Klondike over the trail across the mountain. The gold fever almost tempted some of the party to push on three hundred miles farther to Dawson, but the memory of lucrative practices at home sobered their judgment; yet, when they left Sitka it was with a feeling of sore need for a lining of gold dust in their empty pockets. Sitka, the once seat of the Russian government in Alaska, the historic town with its ancient, fire-shaded boulevard by the island-gemmed sea, with its library and Russian church, its old samovars and furs and quaintly wrought silver; Sitka, with its row of Indian girls sitting with their finely-woven baskets under the shade of the pine trees, proved too much for the prudence of the company, and after paying their respects to the Governor and his wife, they bought generously, enthusiastically, frantically, mocassins and baskets and totem poles.

Through the courtesy of the officers the famous Treadwell mines were thrown open to the party, and they stood at the rim of the great Glory Hole, where miners that looked like ants crawled around and blasted quartz, then carried it up the steep rocks, where it was crushed and washed and the rich pay dirt collected for final smelting.

But the most wonderful experience of all was on

afternoon spent in a sea of icebergs, where the shining Foster Glacier was pushing its tall white ice-cliffs into the sea. The Jefferson slowly made its way between the great blue floating grottoes and towers, then put off life-boats with the party, who were cautiously rowed between the ice-floes to the pebbly beach at the foot of the Taku Glacier. There the stout and slim alike were carried ashore on the sailors' backs. And after a walk of a mile or more over the rubble of the terminal moraine they climbed the glassy slope of this retreating glacier that now melts and deposits its burden of stones before it reaches the sea. To share adventures with those with whom heretofore one has merely shared scientific opinions is to establish a friendship between men of widely different residence that would otherwise take years to form.

OBITUARY.

Dr. M. S. Graham, of Rochester, died in that city last week, aged fifty years. He was chief surgeon at the Hahnemann Hospital there and conducted a sanitarium. He had been President of the County Medical Society, and was a member of a number of other medical societies and a prominent Mason.

Dr. Robert Maitland Petrie died suddenly at his home, Jersey City, last week, from heart disease. Dr. Petrie was born at Liberty, N. Y., in 1850. He was a son of the Rev. Dr. Petrie, who in 1856 became the first pastor of the first Presbyterian Church erected in Jersey City. Dr. Petrie was educated at Princeton and afterward studied medicine at the University of Pennsylvania. He was a member of the State Pathological Society, and was regarded as an authority on heart disease.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, held at San Francisco, Cal., July 5, 6 and 7, 1905.

The President, Geo. Ben Johnston, M.D., of Richmond, Va., in the Chair.

After a brief executive session, Dr. Emmet Rixford, of San Francisco, First Vice-President, took the chair, and President Johnston delivered his address.
